Care of the Critically ill. Third edition

S. M. Ayres, A. Schlichtig and M. J. Sterling. 177 × 252 mm. Pp. 404. Illustrated. 1988. London: Wolfe Medical. £25.00.

This revised edition aims to describe the 'science and art of critical care' and provides a basic textbook for those involved in the care of patients on intensive therapy units. The book is readable and although not written specifically for surgeons should be of interest to those not already fully *au fait* with the overall management of seriously ill surgical patients.

The fundamentals of cellular metabolism, cardiovascular, respiratory and renal physiology and the pathophysiological changes that occur in response to injury and disease are clearly described. The authors' view on the current optimal treatment of the critically ill is given with appropriate justification. In addition there are chapters on multiple organ failure, the central nervous system and nutritional alterations that occur in these patients, specific aetiological factors (including sepsis, burns, trauma and AIDS), and an overview of the organization of critical care. The illustrations are good, but brief summaries at the end of each section or chapter would have been helpful.

The book was originally based on experience with cardiac surgery patients which may explain its bias away from the general surgical patient. There is no discussion of the surgical aspects of management. The role of sepsis, particularly intra-abdominal infection, is neglected, and its investigation and management are not covered. The pathophysiological effects of endotoxaemia and its importance in 'septic' patients is barely mentioned.

Despite these reservations the book can be recommended as a basic non-surgical text for those surgeons involved in care of the critically ill.

A Colour Atlas of Trans-abdominal Gastric Fundoplication

J. G. R. Cumming. 265 × 196 mm. Pp. 61. Illustrated. 1988. London: Wolfe Medical. £19.00.

The Wolfe series of atlases of single surgical procedures is probably familiar to most surgeons by now. I must confess that I often find colour photographs of operative surgery disappointing as a guide for technique. Fine detail may disappear in a sea of red and the photographs have to be well chosen and properly composed to make the point at each stage. Fortunately most of the illustrations in this book are exceptionally clear. There are also a few line drawings which complement the colour plates well and there is no doubt at all about the procedure being performed. I also enjoyed the introductory section on diagnosis and preoperative assessment, which is concise, up-to-date and reasonably practical.

There is, however, one major defect of this book. The authors have chosen a variation of the Nissen fundoplication which is individual and rather dated. Most oesophageal surgeons now accept that the 'floppy' version of the Nissen described by Donahue and Bombeck 11 years ago is an essential modification to reduce the side effects of dysphagia and gas bloat. A fundamental problem of all surgery for gastro-oesophageal reflux is that it is inherently variable and this affects the end results. A monograph on the Nissen which ignores the variations is not, in my opinion, a good guide for the trainee.

Lecture Notes on General Surgery. 7th ed.

H. Ellis. 137 × 24 mm. Pp. 459. Illustrated. 1987. Oxford: Blackwell Scientific. £9.95.

Reviewing a 'classic' undergraduate textbook is not easy since thousands of students have voted with their feet and can attest to its worth. To see how the seventh edition has changed, I reached for my first edition, dated 1965. At first sight hardly anything seemed to have changed apart from the addition of two chapters. The first addition deals with postoperative fluid and electrolyte balance and perioperative nutrition, the other with transplantation surgery.

Since the first edition typographical errors have been corrected and when new developments occurred, for example the introduction of H_2 antagonists and highly selective vagotomy in the field of peptic ulceration, they have been added to existing text rather than a full rewrite to give a new perspective. Thus, surgery for peptic ulcer is relatively overstressed compared with medical treatment and within the surgical discussion gastrectomy is still overemphasized compared with vagotomy. Also, there is no mention of mucosal defence mechanisms in the aetiology of peptic ulceration, and drugs which are non-antisecretory but highly effective at healing ulcers are omitted. Other inappropriate lack of emphases include the role of sclerotherapy for oesophageal varices and transurethral resection for prostatic hypertrophy.

Unfortunately this seventh edition reads as though it was written at the time the sixth edition was produced—in 1983. If this book is to remain a 'classic' for the aspiring student, a radical rewrite will be necessary to get rid of the dead wood rather than simply grafting a few new sentences for each new edition. One of the few examples in the book where an update has been successful is the extensive additions to the section dealing with breast cancer. Perhaps the distinguished authors will consider taking on board a new recruit to edit the next edition.

Postmastectomy Reconstruction. Second edition

T. D. Gant and L. O. Vasconez. 174 × 258 mm. Pp. 298. Illustrated. 1988. Baltimore: Williams and Wilkins. US$68.95

There will be those who view a publication like this as an enjoyable essay into surgical extravaganza without relevance to modern management of breast cancer. After all, we all know that mastectomy belongs to a bygone age and that conservation is all the rage: except, of course, for the patients who prefer it, for the lesions not suitable for local excision on grounds of size or position, for treatment of local recurrence after conservation therapy and for the few cases where prophylaxis is required. No wonder there has been a need for a comprehensive volume on postmastectomy reconstruction, not just for plastic surgeons but, I would suggest, any surgeon interested in obtaining the best outcome for the patient. But is this the book?

Gant and Vasconez have assembled 20 contributors to write 20 chapters in 298 pages. The chapters vary in their value—the early chapters on philosophy, primary treatment, outcome and aetiology hardly do justice to the enormous literature on these subjects and it is sad to see a continued belief in the value of 5-year survival as an indicator of outcome in early disease. Michael Lagios has provided a workmanlike review of the pathological features of breast disease. The chapter on arterial blood supply considers veins, lymphatics and nerves but physiology doesn't deserve a mention. The meat of the book lies in its handling of matters related to reconstruction. I particularly enjoyed the chapters on breast implants by Boyd Burkhardt, tissue expansion by Gibney, and Jarrett's chapter on prophylactic mastectomy because of its honest attempt to discuss the complications. Those not familiar with the latissimus dorsi, thoracoepigastric and transverse rectus flaps will find these sections helpful but they will be of limited value to established plastic surgeons who may find more in the chapters on topology, and the description of less commonly used techniques such as the upper rectus flaps, free grafts and breast shaving. The management of the contralateral breast is dealt with in a reasoned manner; the chapter on nipple areola complex reinforces my belief that when a lot of procedures are used with the same objective none of them is entirely satisfactory.

Overall the book is good on the 'how', although some of the illustrations (all in black-and-white, mostly photographs with some line drawings) lack quality of reproduction. It is less good on the 'when and why' to do reconstruction and on which procedure to choose. Regrettably no attempt has been made to grapple with the difficult but vital aspects of patient views on the results of this type of surgery—perhaps the next edition will put this right.

This book will appeal mainly to the surgeon with an interest in breast disease who either performs reconstructive surgery or who wants to refer patients for it. It represents a good state-of-the-art essay on the available techniques.

Patient Care in Vascular Surgery

J. W. Hallett. 134 × 214 mm. Pp. 306. Illustrated. 1987. Edinburgh: Churchill Livingstone. £16.50.

This chunky paperback is intended to be a practical guide for students, residents, technicians and nurses. It encompasses arterial and venous, but not lymphatic, disease. The rapid rate of progress made in vascular surgery has necessitated extensive revision of this second edition and it is up to date. The condensed but readable text contains a mass of information and each chapter has an extensive bibliography. Anatomy and pathology are very briefly mentioned. The strong points are patient assessment, practical management and postoperative care. It is well organized, with headings, tables, diagrams, line drawings and graphs.

The emphases are slightly different from those one might expect in the UK: almost nothing on the recording of patient histories and differential diagnosis; a 26-page chapter on laboratory tests; relatively slight attention to venous disorders; a greater willingness to operate on claudicants and patients with asymptomatic carotid lesions. However, one suspects that these trans-Atlantic differences are becoming much less marked than even 5 years ago. This is the sort of book that should lie around on the desk or coffee table and be well thumbed wherever vascular surgery is practised.

Surgery Annual 1988

L. M. Nyhus. 167 × 240 mm. Pp. 355. Illustrated. 1988. East Norwalk, Connecticut: Appleton and Lange. US$69.95.

There are 16 chapters in this annual review, 11 from North America, three from the UK and one each from Sweden and France. This year there seems to be a particular emphasis upon gastrointestinal surgery, but, as always, there is considerable variety in the topics covered and there is likely to be something of interest for all surgeons.

There is an excellent review of the management of portal hypertension by Rykers who is a firm proponent of the distal splenorenal shunt. He suggests that patients with poor results usually reflect the inexperience of the surgeons performing the operation, but from previous experience many surgeons would be wary of such a conclusion having heard a similar claim made for other procedures that were ultimately found to be inherently faulty.

Warshaw and Schapiro provide a very complete review of the relationship between pancreas divisum and pancreatitis, concluding that obstructive pancreatitis occurs only in patients with pancreas divisum who have stenosis of the accessory papilla. They are able to achieve dorsal pancreatography in 90 per cent of patients which is much higher than the reviewer's experience. To support their contention that it is the combination of stenosis of the accessory papilla with pancreas divisum that is responsible for the dorsal pancreatitis, they emphasize the rarity of pathological changes in the anatomy of the dorsal duct accompanying anomalous changes. Their diagnosis of obstructive pancreatitis rests mainly upon the test that they have devised which records changes induced by secretin in the ultrasonic diameter of the dorsal pancreatic duct and they review in a very reasonable manner their extensive experience. This chapter should certainly be read by surgeons treating patients with unexplained abdominal pain.

Bismuth and his colleagues describe the development of segmental resection of the liver to which they have contributed so much. Classical resections in which excessive amounts of normal parenchyma may be removed are being replaced by segmental excisions based upon portal and arterial blood supply. Although the surgical resections involved are well described, as the authors emphasize, peroperative ultrasonography is an essential component of segmental excision and I would have preferred more illustrations of this technique in this chapter.

Bengmark and Jeppsson describe their 20-year experience of various forms of hepatic arterial ligation in the treatment of hepatic tumours. They recognize that the results have been disappointing and suggest that the major reason for this is the development of arterial collaterals. However, they conclude enthusiastically with their initial results of repeated transient de-arterialization using a balloon occluder.

Cahill and Pain review renal failure and other complications produced by endotoxin in obstructive jaundice. This is a useful review but from the content I suspect that it was written in the latter half of 1986 and since then there has been more interesting work in this field. During the next decade major developments will be made in the investigation and treatment of disorders of gastrointestinal motility.

Pellegrini and Allegra provide an up-to-date review of gastric emptying and the problems encountered in surgical patients.

In their chapter on 'Respiratory function in surgical patients', Pett Jr and Wernly remark 'the quality of care . . . varies among physicians. It is refreshing to see residents and surgeons continue to resist transferring the responsibility of peri-operative management to specialists'.

I concur with the concept that a patient is admitted under the care of a single clinician who must be responsible for all major decisions and with the concept that surgeons must be knowledgeable about the function of all organs in the body. However, changes in pulmonary and cardiac function can occur with dramatic suddenness, particularly in the postoperative period, and may require instantaneous treatment. Many surgeons would be unhappy to transfer the ultimate responsibility of care for their patients but would be happy to share responsibility, particularly in fields where there may be individuals with more expert knowledge.

I enjoyed reading this, the twentieth volume, of this well known book. The topics chosen by Professor Nyhus for this edition were provocative and pertinent.

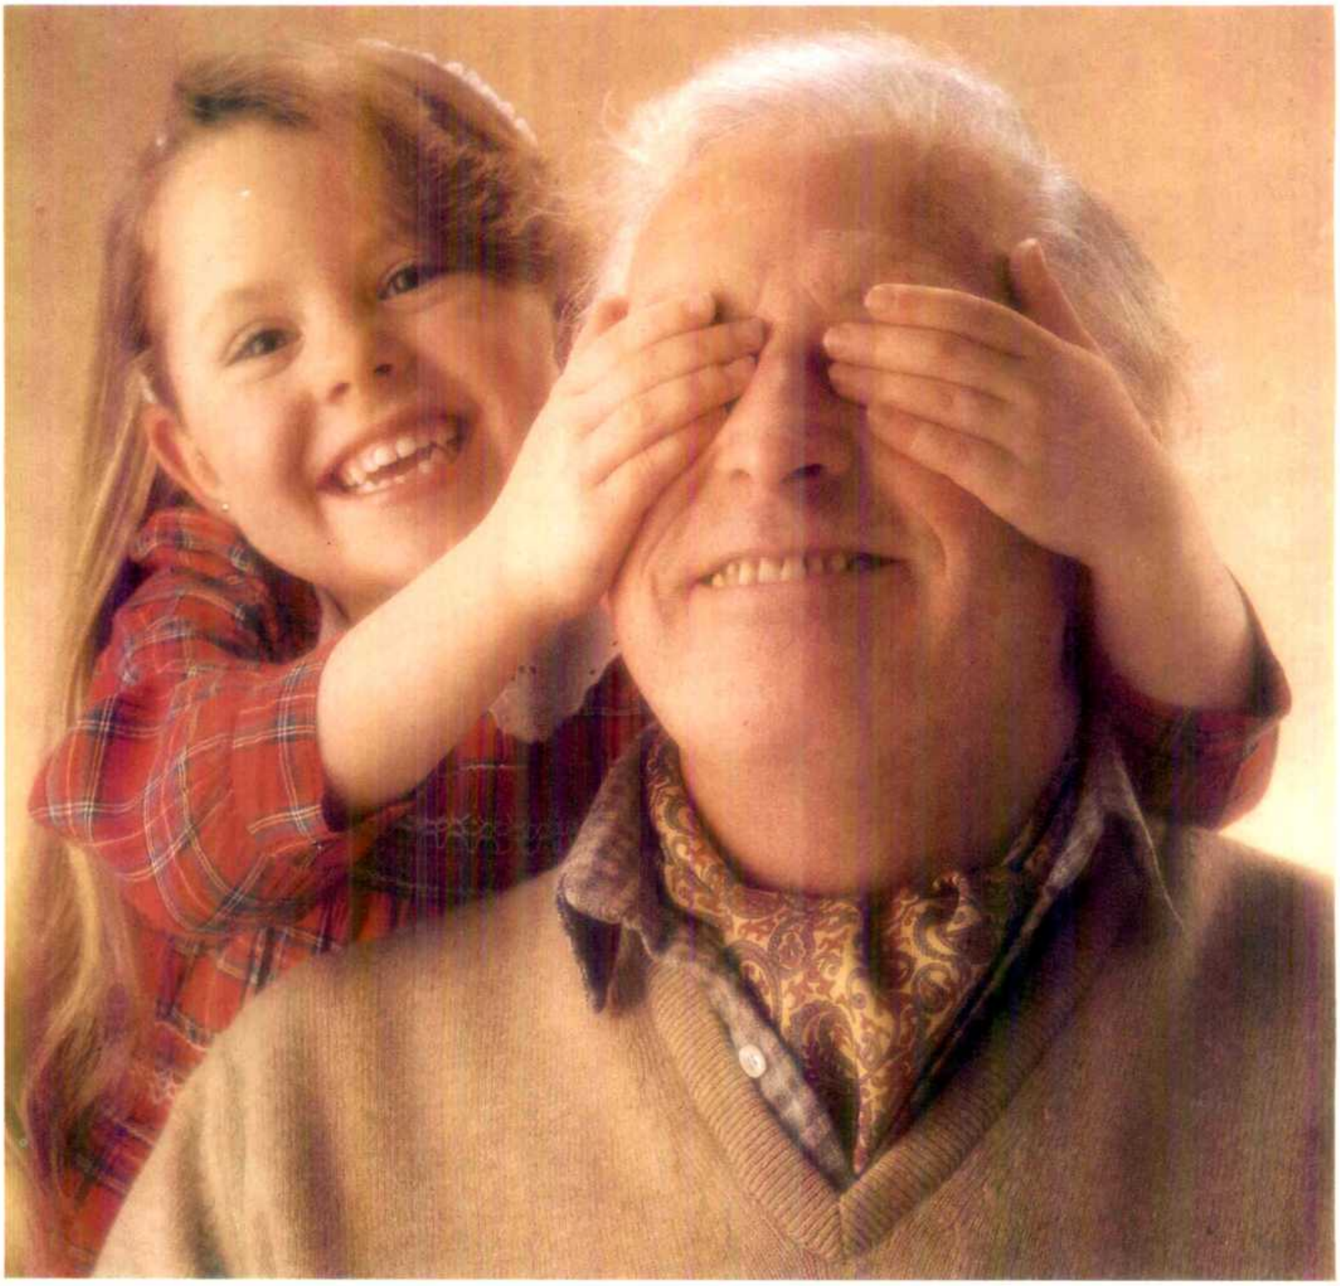
The British Journal of Surgery

Volume 76, Number 4, April 1989

Guess which prostate cancer treatment most patients would choose.



In a recent study[1], 57 prostate cancer patients were invited to participate in choosing their treatment. All were informed that the two treatments available, sub-capsular orchidectomy or 'Zoladex', were similar in efficacy and side effects. 49 of the patients (86%) opted for 'Zoladex'.

A recent trial[2] has established the equivalence of 'Zoladex' to orchidectomy.

Zoladex

goserelin

Effective therapy without surgery.

▼ 'ZOLADEX' PRESCRIBING NOTES.

Use: Prostate cancer suitable for hormonal manipulation. **Presentation:** A sterile depot containing goserelin 3.6mg. **Dosage and administration:** One depot injected subcutaneously into the anterior abdominal wall every 28 days. **Precautions:** Care with patients at particular risk of developing ureteric obstruction or spinal cord compression. Consider initial use of an anti-androgen at the start of therapy. **Side effects:** Hot flushes, decrease in libido and occasional breast swelling and tenderness. Skin rashes (generally mild). Occasional mild bruising at injection site. Initial transient increase in serum testosterone may cause temporary increase in bone pain. **Product licence number:** 29/0198. **Basic NHS Price:** £114.00 per depot. 'Zoladex' is a trademark. Further information is available from: ICI Pharmaceuticals (UK), Southbank, Alderley Park, Macclesfield, Cheshire SK10 4TF.

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer-Verlag 1981: 123–63.

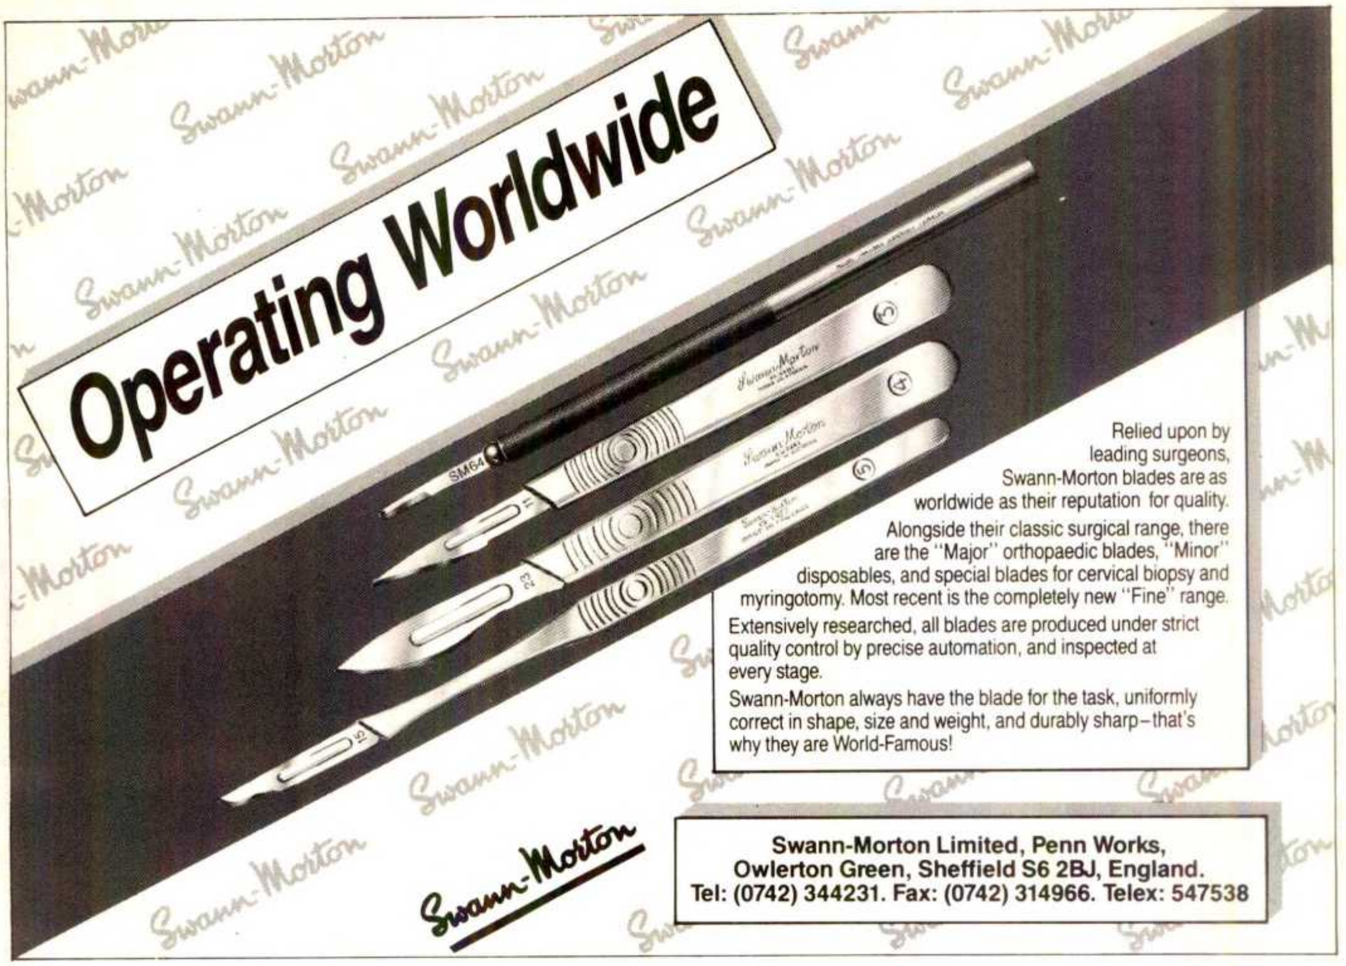
The Vascular Surgical Society of Great Britain and Ireland

The cover picture shows the chain of office of The Vascular Surgical Society of Great Britain and Ireland.

The President of the Society is Mr J. H. Shoesmith, FRCS of the Royal Victoria Infirmary, Newcastle upon Tyne, UK.

The Secretary of the Society is Mr C. V. Ruckley ChM, FRCS, Ed. Enquiries should be addressed to Mr Ruckley at the Vascular Research Office, University Department of Clinical Surgery, Royal Infirmary, Edinburgh EH3 9YW, UK.



Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality. Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp–that's why they are World-Famous!

HEINEMANN MEDICAL BOOKS

announces the publication of . . .

SCIENTIFIC FOUNDATIONS OF SURGERY Fourth Edition

Edited by
James Kyle DSc, MCh, FRCSI
Consultant Surgeon, Aberdeen Royal Infirmary, Clinical Senior Lecturer in Surgery, University of Aberdeen, Examiner in Surgery at the Royal College of Surgeons in Ireland and Royal College of Surgeons, Edinburgh.
and
Larry C Carey
Professor of Surgery and Chairman, Department of Surgery, The Ohio State University, Clinical College of Medicine, Grant Medical Center, Colombus, Ohio.

'The appearance of the first edition was a landmark and this edition maintains the high standard in presenting the disturbances of physiological processes which causes diseases in the various body systems'
Annals of the Royal College of Surgeons of England

'This edition is yet another success'
British Journal of Surgery

'An excellent textbook which will continue to be essential reading for any FRCS candidates in this country and will also provide intellectual stimulation for their more advanced colleagues and examiners.'
British Journal of Hospital Medicine

(From reviews of previous editions)

Scientific Foundations of Surgery is the standard text on its subject internationally for candidates for FRCS and equivalent examinations internationally, trainee surgeons, practising surgeons and others employed upon surgical research.

Professor Kyle has been an editor of this remarkable book since it was first published in 1967. Professor Carey, who joins him for the 4th edition, was recommended for the post of USA editor by the previous American co-editor, Professor Hardy.

Radiotherapy Titles from Butterworths

Megavoltage Radiotherapy 1937–1987

(BJR Supplement No 22)

Editors **P N Plowman** and **A N Harnett** Both at St Bartholomew's Hospital, London, UK

Megavoltage Radiotherapy 1937–1987 is the proceedings of a conference held to mark the 50th anniversary of megavoltage radiotherapy at St Batholomew's Hospital and contains 15 full papers from invited speakers and over 100 abstracts. It is a significant reference work on current practice in radiotherapy, whilst offering insights on future trends as well – a vital publication for clinicians and all those involved in cancer management.

Contents: Introduction • Opening plenary section • Precision in radiotherapy • CNS tolerance and clinical results • Abdominal organ tolerance and radiotherapy • Current status of electron therapy – clinical and physical aspects • Paediatric radiotherapy • Breast conservation • Interstitial radiotherapy • Current concepts in fractionation • Response predictors in radiotherapy • Quality assurance in radiotherapy • Xenografts and the radiobiology of human tumours • Ocular radiotherapy • Total body irradiation • Poster presentations • Index to authors

EST OF SCOTLAND COMMITTEE FOR POST GRADUATE MEDICAL EDUCATION

PRIMARY FRCS COURSE

18 September to 8 December 1989
in the University of Glasgow

This 12 week Course is designed specifically for candidates preparing for the Primary FRCS Examination and consists of lectures and vivas in Anatomy, Bacteriology and Immunology, Biochemistry, Physiology, Pharmacology, Pathology and Virology. The clinical relevance of basic science topics is developed in a series of demonstrations and there is considerable emphasis on MCQ and viva practice.

The Course fee is £650

Reasonably-priced accommodation can also be arranged.

Application forms and further details are available from:

SURGICAL RESEARCH COMMUNICATIONS

AIMS AND SCOPE

The aim of this journal is to present all aspects of surgical research. Both clinical and laboratory-based work is reported. Communications from surgeons-in-training who are involved in a period of full-time research are welcome.

The journal publishes original full length articles of high scientific standard, with appropriate trial design and analysis, in fundamental surgical science. Retrospective reviews and short reports of negative results are also included and, occasionally, didactic case reports.

In addition, this journal publishes reviews, selected symposia proceedings, reports of significant meetings, correspondence, and book reviews.

A 'camera-ready' rapid communications section is also included.

A SELECTION OF RECENT AND FORTHCOMING PAPERS

Peritoneal Fluid: Assessment of the Severity of Peritonitis, ***H. Wacha, H. Knothe, V. Schäfer*** and ***H.M. Labus*** • Anticardiolipin Antibodies: A Risk Factor in Peripheral Arterial Thrombosis? ***J.J. Earnshaw, N.C. Armitage, N.P. Richards, P.J. Powell, B.R. Hopkinson*** and ***G.S. SUBSCRIPTION INFORMATION

Current volume block: volume 6–7, 1989
4 issues per volume ISSN: 0882-9233
Corporate library subscription price per volume: $200.00
University library subscription price per volume: $128.00
Individual subscription price per volume: $68.00*

*In the United States and W. Europe the individual subscription rate is inclusive of postage and handling and is applicable only to individuals whose library already subscribes OR individuals who certify the journal is for their own personal use and provide their home address for mailing. In both cases the individual must order directly from the publisher and pay by personal check or credit card. Individuals in other territories should contact the publisher or its local agent for prices.

The journal is available to members of certain societies at a substantial discount. Please contact the publishers for details.

SPECIAL ANNOUNCEMENT

Two prizes of $500.00 will be awarded for the best papers submitted with Surgeons-in-Training as first author.

The first prizes will be awarded in the summer of 1989.

Please mark on your paper if you wish it to be considered for the next prize.

A perspective for the management of variceal bleeding

The 1980s have seen a major expansion in therapies available for the prevention of recurrent variceal bleeding. Drug therapy[1], endoscopic sclerotherapy[2], and liver transplantation[3] have greatly extended the range of options beyond the previously available surgical methods of total portal–systemic shunts, selective variceal decompression, and devascularization procedures. The dilemma which the clinician now faces is how to choose the right therapy for the right patient at the right time. This article summarizes the practice and philosophy which have evolved at Emory University Hospital in this decade with the availability of all modern methods of treatment.

The major questions to be addressed are, firstly, what is the patient's risk of rebleeding and developing liver failure and, secondly, what is the risk of rebleeding and liver failure with the alternative methods of treatment? The first question requires complete evaluation of the patient and the second a knowledge of the outcome when each method is used to treat patients with different aetiologies and stages of cirrhosis.

Patient evaluation will assess rebleeding risk primarily by endoscopy: larger variceal size and endoscopic risk factors such as red wale markings and cherry-red spots are indicative of increased risk of rebleeding. Angiographic assessment of portal hypertension with venous phase visceral arteriography will demonstrate variceal inflow paths while wedged hepatic vein pressure will measure the degree of portal hypertension. The aetiology of the portal hypertension will influence the outcome from variceal bleeding; for example, patients with portal vein thrombosis have a much better prognosis than those with cirrhosis. In the patient with cirrhosis, a combination of clinical and laboratory parameters as used in Childs' classification provides a useful working definition of severity. However, a more profound judgement of the stage of the liver disease can be achieved from knowledge of the morphological status at liver biopsy, measurement of liver volume, and measurement of hepatocyte function, e.g. by galactose elimination capacity. The important differentiation is to distinguish between patients with reversible disease (alcoholic or chronic active hepatitis) and those with end-stage cirrhosis. Therapy for these subsets will differ.

The major points emerging from reported studies of the available methods of treatment as interpreted by this author are as follows. Propranolol has established a place in the prevention of the first bleeding episode: it will reduce portal hypertension[4]. Propranolol may also have some benefit in reducing rebleeding in good-risk alcoholic patients and in patients with portal hypertensive gastropathy[1]. Endoscopic variceal sclerosis is a widely applicable therapy but has a 30–60 per cent rebleeding rate and an ultimate failure rate of 15–30 per cent: it has no adverse effect on liver function[2,5]. Total portal–systemic shunts will control bleeding, but have an unacceptably high rate of hepatic failure; they are best tolerated by the patient with alcoholic cirrhosis[6]. Selective variceal decompression has a bleeding control rate as good as that achieved by total shunts ($\geqslant$90 per cent), and is associated with better maintenance of hepatic function: its physiological goals are best achieved in patients with non-alcoholic disease. Devascularization procedures have a significant rebleeding rate (up to 40 per cent) and maintain hepatic function but require follow-up endoscopic surveillance. Liver transplantation treats both the portal hypertension and the hepatic failure in patients with end-stage disease. It can be achieved with an acceptable mortality and is a viable therapeutic option.

The current problem is, therefore, how to use these therapies to best advantage in optimal patient care. The current management scheme which has evolved in our practice is as follows[5]. The patient should be resuscitated and stabilized after the acute bleeding episode; the use of sclerotherapy at this time has markedly reduced the need for Pitressin® (Parke Davis Medical, UK) and/or tamponade. Complete patient evaluation, based on the outline given above, can be completed over the next 3–4 days. In patients with cirrhosis, chronic sclerotherapy is a rational first-line treatment[5]. We consider that this should be carried out by, initially, frequent (weekly or bi-weekly) sessions until variceal obliteration is achieved, followed by less frequent surveillance/therapy sessions. Exceptions to this line of management are made for: (1) good-risk patients (Childs' A, galactose elimination capacity >300 mg/min) in whom the 30–60 per cent rebleeding risk of sclerotherapy may be unacceptable (we

0007–1323/89/040323–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

consider that such patients should be offered a distal splenorenal shunt); (2) patients with portal vein thrombosis, who can expect a normal lifestyle and expectancy after a successful distal splenorenal shunt; and (3) patients with gastric varices or portal hypertensive gastropathy not amenable to sclerotherapy (we consider that they should have surgery).

When variceal bleeding is controlled by sclerotherapy, continued monitoring of the liver disease is an essential component of further management. In many patients, control of bleeding and stable disease combine to give a return to a normal lifestyle. In some patients, progression of disease may ultimately lead to liver transplantation.

When variceal bleeding is not controlled by sclerotherapy, further therapy is largely dictated not only by the bleed itself but also by the underlying disease. The definition of a sclerotherapy failure is the most vexing question in this field at the present time. Such treatment failure cannot be decided solely by the number of rebleeding episodes or the blood transfusion requirement. At one end of the spectrum a patient who dies from a single rebleeding episode is clearly a sclerotherapy failure, while at the other end is a patient who has numerous rebleeding episodes which are readily controlled by further sclerotherapy and who ultimately achieves freedom from further bleeding. Sclerotherapy failure must rather be decided by (1) the overall rebleeding pattern taking into account the severity and site of rebleeding and any mucosal changes and (2) the life-threatening nature of further bleeding, which may be dictated not only by the bleed itself but also by factors such as geographic remoteness, patient compliance with treatment and underlying disease severity.

When the patient and clinician believe that sclerotherapy is no longer adequate therapy, we consider that good-risk patients should be managed by a distal splenorenal shunt and poor-risk patients considered for transplantation. Data from our randomized study comparing distal splenorenal shunt with sclerotherapy show that successful surgical salvage of sclerotherapy failures leads to the best survival statistics in the group originally randomized to sclerotherapy[5]. In this study one-third of patients ultimately failed on sclerotherapy because of rebleeding; half of these rebleeds occurred in the first few months with a second peak after 2 years. In most patients sclerotherapy buys the time to allow individuals to declare the natural history of their disease, and gives the clinician the time to make a logical decision on further therapy.

Total portal–systemic shunts in our practice are limited to life-saving 'salvage' operations in the patient with continued massive acute bleeding. In this setting our preference is for a large bore (16 mm) interposition portacaval shunt. Devascularization procedures are only used in patients in whom there are no veins suitable for selective shunt and in whom bleeding is not controlled by sclerotherapy, usually because it is from gastric varices. This option is preferred to total shunt in the elective setting, particularly when followed by surveillance endoscopy and/or sclerotherapy.

In summary, there have been major changes in the field of therapy available for variceal bleeding in the past decade. In our practice approximately 100 new patients are referred each year for definitive therapy to prevent recurrent variceal bleeding. The breakdown of definitive methods used approximates as follows: sclerotherapy, 50 patients; distal splenorenal shunt, 40 patients; transplantation, ten patients. Propranolol will be used as adjunctive therapy in a minority of these patients. Other surgical procedures will be used in urgent cases, and occasionally for unusual problems. However, practices change and evolve. By the year 2000 . . . ?

Tamoxifen comes of age

Invasive breast cancer, once it has become palpable, is a potentially fatal disease. Malignant cells are likely to have seeded by vascular and lymphatic routes and to have formed 'micrometastases' in systemic sites and in regional lymph nodes. Because of the slow-growing nature of the disease it may be many years before these micrometastases become clinically manifest; nevertheless, once the disease has spread systemically local treatment, no matter how radical, cannot be curative. There is good evidence that there is a threshold of size at which invasive cancer is likely to have metastasized. From histopathological studies[1] this was initially believed to be 0·5 cm, but more recent information related to mammographic screening suggests that 1·0 cm is a more reasonable estimate[2]. It is in the detection of the small invasive (as well as the non-invasive) cancers that mammographic screening has most to offer, and there is now adequate evidence that screening reduces the number of deaths.

But what of the larger invasive tumours for which systemic therapy offers the only real hope of long-term cure? One form of systemic therapy is tamoxifen, a substituted triphenylethylene compound, the antioestrogenic effects of which were first described by Harper and Walpole[3] in 1966. Its value in women with advanced breast cancer (both local and systemic) is now firmly established. Remission is induced in 30–40 per cent of women to whom it is administered as first-line therapy. In controlled randomized trials its action was found to be similar to that of pharmacological doses of diethylstilboestrol, but unlike stilboestrol it had no troublesome side-effects. For this reason it is now not only the agent of choice for those patients who develop so-called recurrent disease but is appropriate adjuvant therapy in primary disease.

Adjuvant therapy

It is now confirmed that adjuvant tamoxifen benefits women over 50 years of age with primary breast cancer[4]. A recent over-view pooling the results of 28 separate randomized trials, which included more than 16 000 women (3782 deaths), has indicated that tamoxifen given for 1–2 years reduces the annual mortality rate by (mean ± s.d.) 16 ± 3 per cent, a highly significant fall. In women over 50 years of age the reduction was 20 ± 3 per cent; in absolute terms this represents an increase in survival at 5 years from 68 to 73 per cent, a difference of 5·7 ± 1·0 per cent. A beneficial effect was observed in both node-negative and node-positive women of this age group but was not observed in women younger than 50 years of age. However, the number of younger women was small and most had also received adjuvant chemotherapy in both arms of the trials.

It is relevant to ask whether the administration of tamoxifen as immediate adjuvant systemic therapy has any advantage to its delayed use for recurrent disease. This question has been addressed in the Scottish tamoxifen trial[5] in which 1312 evaluable patients with primary cancer (242 premenopausal women without proven node involvement and 1070 postmenopausal women with negative and positive nodes) were treated by mastectomy and randomized to receive immediate tamoxifen (20 mg daily) for 5 years or to be controls. In the control group tamoxifen was to be given on recurrence of disease and this has been first-line therapy in more than 90 per cent of such patients. A highly significant effect of immediate tamoxifen therapy on survival and on recurrence-free survival was still observed. This effect occurred not only in postmenopausal women with negative or positive nodes but also in premenopausal women with negative nodes. A recent report from the USA supports this finding in node-negative (and oestrogen-receptor positive) disease[6]. A subset of 104 women separately randomized for the pilot study preceding the trial have all been followed up for more than 5 years, and the reduction in the 5-year mortality rate approximates to 40 per cent. It is important to know whether or not tamoxifen should be administered for the rest of the patient's life and a second randomization is now being carried out at the end of the 5-year period, women being allocated either to continue or to stop taking the drug. This is a most important addition to the study.

Pharmacological action

Tamoxifen acts by competitive inhibition of the binding of oestrogen by its receptor. Unlike the oestradiol–receptor complex, the tamoxifen–receptor complex is ineffective and fails to stimulate the genome. In advanced disease there is a good relationship between the oestrogen receptor status of the tumour and the response to therapy. The relationship between oestrogen receptor status and the reduction in mortality achieved by adjuvant tamoxifen is being examined in several trials. A recent analysis of the Scottish trial suggests that while there may be a trend in favour of patients with oestrogen receptor-rich tumours (>100 femtomoles oestrogen receptor per

0007–1323/89/040325–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

milligram protein) having a greater reduction in risks of mortality and recurrence than those whose tumours are receptor-poor or negative, this is not significant (H. J. Stewart, personal communication). This finding is in accord with the report of the NATO trial[7] but not with that from Denmark[8]. Further study is required.

Patients who will benefit

It is clearly important for cost-effectiveness that tamoxifen should not be given to patients who are unlikely to benefit from its use. The over-view of trials referred to above also considered the results of 31 trials (9069 women) in which chemotherapy was given to one arm. A significant reduction in the annual mortality rate was again observed, and was highly significant in women under the age of 50 years. Should such women not be responsive to tamoxifen (and more information is required to clarify the potential benefit of tamoxifen in this age group) they should not be denied chemotherapy, which is best given as CMF (cyclophosphamide, methotrexate, 5FU).

In patients with primary disease, the tumour in the breast is the only available monitor of the effectiveness of systemic treatment. It is logical to suggest that trials should be instituted in which systemic therapy is the first treatment given, local therapy being reserved until the response of the tumour has been assessed. This is a policy that we are studying in large, but still operable, primary tumours[9], and which is also our preferred option in elderly and frail patients with primary disease. Two randomized controlled studies have now been reported indicating that the initial use of tamoxifen in such elderly patients (reserving surgery for the non-responding tumour) does not compromise survival[10,11]. Our current policy is to assess both the response to tamoxifen and the need for local therapy at 3 months.

The logic of this approach is strengthened by the availability of fine needle aspiration cytology. Not only can the diagnosis of cancer be confirmed but histochemical assays of oestrogen receptor (and if desired other parameters of cell type and function) can be performed. In our elderly patients with primary tumours, the relationship between immunohistochemical assays for oestrogen receptor and the response to tamoxifen has proved to be encouraging. In a series of 52 patients, only one of 21 tumours with less than 25 per cent of the cells staining for receptor in fine needle aspirates responded by a reduction in tumour size following tamoxifen treatment (D. J. Gaskell, R. A. Hawkins, K. Sangster, A. P. M. Forrest, manuscript in preparation).

It would appear that tamoxifen, with its absence of side-effects, is the systemic treatment of choice for primary breast cancer. However, this is so only in those patients likely to benefit: the next step must be to define who these patients are. Until a laboratory test to do so has been validated, it would appear reasonable, at least in selected patients, to test the efficacy of the drug before removal of the only measurable sign of disease, that is the primary tumour.

This review examines the effect that a small chromosome deletion affecting a specific DNA sequence may have in producing a state of 'hemizygosity' for a gene or genes, and so triggering malignancy of the cells concerned. The association between such deletions and a variety of cancers will be considered and the implications for clinical practice will be outlined.

Keywords: Cancer, chromosome deletions, oncogenes

The involvement of genetic factors in the aetiology of cancer was first clearly stated by Boveri in 1914[1], who had observed that abnormalities of the mitotic cycle of sea urchin eggs frequently preceded abnormal growth. Later, in 1930, Winge[2] suggested that a population of cancer cells represents the result of a single genetic event, and proposed the 'stem cell' concept. Many years had to pass before cytogenetic[3,4] and biochemical analysis[5] of cancer cells made it possible to demonstrate conclusively that all cells of a tumour are cloned from a single cell and that, in the course of their proliferation, they may acquire new characteristics and ultimately differ from the parental cells.

The concept that tumorigenesis is a multistage process, which involves changes at gene level, has gained new emphasis with the discovery of the oncogenes and their role in the transformation of normal cells[6,7].

The purpose of this article is to review briefly a single aspect of the association between chromosome abnormalities and cancer: the effect that a small chromosome deletion may have in producing a state of 'hemizygosity' for a gene (or genes), thus triggering malignancy of the affected cells. These recent discoveries have been made possible by the collaboration of oncologists, surgeons and geneticists as many of these small deletions can only be detected when genetic probes are used to test freshly collected cancer cells. Awareness of the unique chromosome deletions associated with each type of cancer and a close working relationship between oncologists, surgeons and geneticists should improve diagnosis and prognosis of cancer patients and, at least in some cases, allow for more effective prevention of the disease in their relatives.

Major types of chromosome abnormalities in cancer cells

At present, several types of chromosome abnormalities have been shown to be associated with cancer (*Table 1*). The most frequent are: (a) reciprocal translocation with or without apparent loss of DNA sequence; (b) non-reciprocal translocation with loss of genetic material; (c) duplication or amplification of chromosomal DNA sequences; (d) deletion of a small chromosome segment resulting in hemizygosity of an allele at one locus[8,9].

Before discussing this last type of abnormality, we will briefly analyse a few examples of the other genetic defects.

Chronic myeloid leukaemia was the first disorder found to be associated with a reciprocal chromosome translocation with no apparent loss of DNA sequence. About 90 per cent of chronic myeloid leukaemia patients have a population of lymphocytes with a small chromosome, 'Philadelphia' (Ph^1), which results from the translocation of a segment of the long arm of chromosome 22 to, usually, chromosome 9. Appreciable loss of DNA in these leukaemic cells could not be detected by conventional techniques[10–14].

Several other types of leukaemia have been shown to be characterized by unique reciprocal translocations[9,15,16]. In acute promyeloblastic leukaemia, for example, the translocation involves the transfer of the short arm (p) of chromosome 15 to the long arm (q) of chromosome 17: $t(15p+;17q-)$. In acute myelogenous leukaemia the defect involves a translocation between chromosome 8 and 21: $t(8q-;21q+)$.

Perhaps the most investigated tumour involving a translocation is Burkitt's lymphoma, where the translocation occurs between chromosome 8 and either chromosome 14, 2 or 22, carrying respectively the genes for the heavy (14) or light (2 and 22) chains of the immunoglobulin gene[13,16,17]. The breakpoints of some of the reciprocal translocations observed in human carcinoma are often very near an oncogene. This has lent support to the hypothesis that, in these patients, tumorigenesis results from the activation of an oncogene, but how this occurs has not yet been established[16].

In some of these reciprocal translocations, genetic material is lost to a varying extent. Other tumours are characterized instead by a duplication of a chromosome or part of it. In many cases, duplications are seen in cancer cells from patients at the terminal phase of their disease, such as in patients with chronic myeloid leukaemia, where, in addition to the Ph^1 chromosome, an extra chromosome 8 or segments of chromosome 17 can be identified by cytogenetic analysis. Partial trisomies have also been observed in solid tumours[8], probably as a result of repeated mitotic abnormalities. As it is not possible to identify a uniform pattern of duplication of DNA segments in these cancers, the present view is that the genes involved in the duplications are not cancer-specific. Consistent with this suggestion is the fact that patients with trisomies of (or part of) chromosomes 8, 9 and 18 do not show an increased incidence of cancer[8]. An exception

Table 1 *Examples of chromosomal abnormalities in human cancer cells*

Abnormality	Examples and comments
Point mutation	Cancer of bladder and several other tumours
Deletion	Retinoblastoma, Wilm's tumour, cancer of lung
Translocation	Burkitt's lymphoma, and at least ten other different cancers
Inversion	Usually associated with other abnormalities
Amplification	Neuroblastoma: double minutes
Breakages, duplication, trisomies	Usually observed in advanced stages of neoplasms

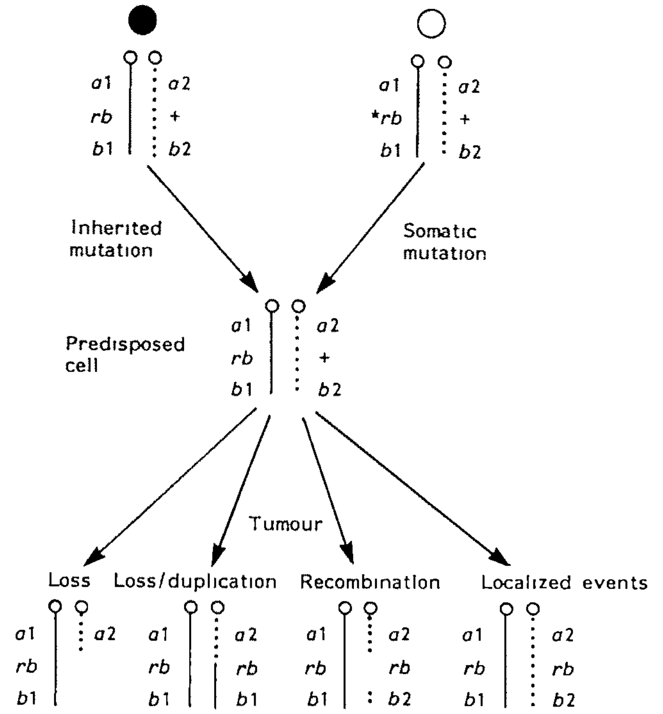

Figure 1 *Schematic mechanisms which can unmask a recessive gene* (rb) *predisposing for retinoblastoma. Patient* ● *has inherited the abnormal gene* (rb), *while patient* ○ *has acquired it in some cells by somatic mutation. Loss of part of the chromosome containing the normal gene* (+) *and a closely linked gene* (b2) *results in hemizygosity for the abnormal* rb *gene. Loss followed by duplication results in the presence of two copies of the* rb *gene A recombination event may also duplicate the* rb *gene Finally, a localized mutation may be responsible for the loss of the normal* (+) *gene, leaving the cell with two* rb *genes In all these instances the regulatory influence of the normal gene* (+) *on the* rb *gene is lost, resulting in cancer of the affected cell. DNA sequences at some distance from the inherited mutation* (*e.g. sequence for* a *or* b *loci*) *defined by restriction fragment length polymorphism can be employed to detect the deletion of the 'cancer' gene*

is trisomy 21, as patients with Down's syndrome have an increased predisposition to leukaemia or other haematological disorders[18,19].

Other duplications are unique to certain types of tumours. For example, neuroblastoma cells may contain several small chromosome segments with unique staining properties. Referred to as homogeneously staining regions or double minute segments, they contain multiple copies of several genes or even a single gene, often conferring resistance to drugs[8,20]. Duplication of oncogenes in double minute segments has also been shown to take place[17,21,22], and this, for example, has been held responsible for causing malignancy in patients with neuroblastoma.

DNA deletions and cancer

The fourth type of abnormality observed with increased frequency in cancer cells is a small deletion affecting a specific DNA sequence. This abolishes the state of heterozygosity of the cell for allelic genes at one locus, and results in a condition of hemizygosity The gene (or genes) present in the DNA sequence homologous to the deleted chromosome segment will thus be present in single 'dose' in the affected cell, and hence the hemizygotic state (*Figure 1*).

So far, at least 15 neoplasms have been found to be often associated with an unique type of deletion, some of which are shown in *Table 2*. The best known examples are retinoblastoma and Wilm's tumour, which occur in both sporadic and hereditary forms[28] A genetic basis for retinoblastoma has been apparent for many years, even though only about 10 per cent of patients have a positive family history[29]. In patients with a family history of the disease, inheritance occurs in a simple autosomal dominant fashion Furthermore, in about 30 per cent of patients with a new mutation, the disease is transmitted to about 50 per cent of the offspring. In 1971, Knudson[30] suggested a provocative theory, that the disease is triggered by two hit-processes, two events affecting the genome of a cell and resulting in its malignancy. Recent studies have clarified the situation and basically confirmed the hypothesis advanced by Knudson: both alleles of the gene must be altered in order for the disease to develop. The first studies were based on cytogenetic analysis of cells from patients in whom retinoblastoma was associated with multiple malformations and mental retardation These patients were shown to have a deletion in the long arm of chromosome 13 (Reference 31). Further investigations showed that a deletion of the band at q14 of chromosome 13 (13q14) could be seen in retinoblastoma cells of patients without the malformation syndrome[32,33]. These and other observations have provided evidence that retinoblastoma results from the inheritance of a germinal mutation which does not, in itself, cause malignancy but predisposes to it, and that a second 'hit' is necessary to trigger malignancy According to the theory, an individual may inherit the predisposing abnormal gene (*rb*, first hit), but only when a second gene change, such as a deletion (second hit), occurs in a susceptible cell (e.g. retinal cell) will the cell become malignant.

The story with Wilm's tumour began with the recognition that cancer cells from patients with a tumour of the kidney, associated with aniridia, had a deletion of the short arm of chromosome 11 at band p13 (11p13)[34]. Abnormality at this site is now considered to be the first event in the aetiology of Wilm's tumour and, as in retinoblastoma, the second event confers either hemizygosity for Wilm's gene (as a result of a deletion) or homozygosity for the abnormal gene (e.g by mitotic recombination) (*Figure 1*).

The body of evidence assembled so far from the study of these two tumours has led to the hypothesis that they originate because one normal suppressor or regulatory gene is lost in the course of the second hit, leaving only the abnormal gene to trigger malignancy. Most recently, Whyte *et al.*[35] have isolated a $10{\cdot}5 \times 10^4$ protein as a product of the retinoblastoma gene. They postulate that this protein might be acting as an 'antioncogene' whose presence initiates suppression of cell division. To support this idea they have observed that a DNA tumour virus, adenovirus E1A, produces a protein which binds the normal $10{\cdot}5 \times 10^4$ protein gene product. Furthermore they speculate that the tumour-inducing properties of this virus lie in its ability to turn off normal cellular suppression by binding the host cell's normal suppressor protein. This idea is supported by the finding that a deletion in the DNA of the tumour virus in the gene which produces the binding protein destroys the tumour-inducing properties of the virus[35,36]. Using probes which identify polymorphic DNA sequences (restriction fragment length polymorphisms) linked to the tumour loci, two other embryonal carcinomas—rhabdomyosarcoma and hepatoblastoma—have

been shown to be due to genetic changes which result in hemizygosity or homozygosity for an abnormal gene[37].

During the last 2 years, other tumours have been found to be associated with unique types of chromosome deletions, which could only be detected using restriction fragment length polymorphisms. In the absence of any knowledge of the gene responsible for a specific tumour, the polymorphism of DNA sequences closely linked to the cancer gene can be exploited to establish the presence or absence of a deletion (see *Figure 1*). This strategy has been employed, for example, to investigate oncogenesis in patients with cancer of the lung, the colon or the breast.

A small deletion of chromosome 3 is the most constant finding in cancer of the lung tissue. Using a large panel of lung cancer cell lines representing all the different histological types (squamous or epidermoid carcinoma, adenocarcinoma, small cell carcinoma, and combined type) Minna *et al.*[38] were able to identify a gene on the short arm of chromosome 3 which may predispose to cancer of the lung. According to this hypothesis, individuals at risk would be heterozygous for this recessive gene, carrying one mutant and one copy of a normal functional gene in each cell. In these individuals environmental factors, in particular cigarette smoke, may produce somatic changes—such as a deletion or a mutation of the normal gene—in a lung cell, thus unmasking the abnormal gene. Loss of the normal gene is suspected to deregulate the expression of a proto-oncogene of the c-*myc* family or other gene controlling the synthesis of growth factor.

Deletion of a DNA sequence at the chromosomal region 3p21 in patients with lung cancer has been confirmed in a recent study[39]. In fact, using a molecular genetic approach, consistent deletion of the chromosome region 3p21 was observed not only in small cell lung cancer but also in all major types of lung cancer investigated. Part of the analysis was carried out using cell lines obtained from the tumours. A series of 16 biopsies from squamous cell carcinoma and 14 adenocarcinomas was also investigated. In several patients where heterozygosity for the selected DNA marker was detected using peripheral blood leucocytes, the tumour cells showed hemizygosity, thus revealing loss of the DNA region (3p21, locus DNF 15 5e). This confirms that somatic mutation of a gene at 3p21 is involved in the development of cancer of the lung.

In the case of cancer of the colon, a single patient was initially observed with a deletion of part of the long arm of chromosome 5 (5q), who, in addition to various developmental disorders, had multiple adenomatous polyps of the large bowel[40]. Linkage analysis of patients with cancer of the colon and their relatives, using a series of genetic probes defining polymorphic DNA segments (restriction fragment length polymorphisms) in the long arm of chromosome 5, has recently confirmed that indeed the familial adenocarcinomatous polyposis gene maps to chromosome 5 (5q21 or 22)[24,41]. In a parallel study, loss of heterozygosity in this DNA region was demonstrated in about 20 per cent of patients with spontaneous colon cancer[42] Thus inherited and sporadic forms of cancer of the colon both result from mutation in the same gene, in analogy with the hypothesis advanced by Knudson[30] for retinoblastoma and Wilm's tumour[43]. Both these mutations act in a recessive form and both normal allelic genes must be altered for cancer to develop. In the sporadic cases both events occur somatically, whereas in the familial cases susceptibility is inherited through germ-line mutation and cancer develops after a somatic change in the homologous allele (*Figure 1*)

Somatic loss of heterozygosity for genes on chromosome 11 has also been observed in some patients with cancer of the breast[25]. Deletions of various DNA sequences of the short arm of chromosome 11 were observed in about 20 per cent of breast cancer tissue biopsies obtained from 56 patients tested, and a significant association was noticed with tumours that lacked oestrogen and progesterone receptors.

Renal carcinoma, the most frequent form of malignancy of the human kidney, usually occurs during the sixth and seventh decades of life. Most tumours are sporadic, but hereditary forms have been described and are characterized by an early onset and bilateral localization. Cytogenetic studies have indicated that the short arm of chromosome 3 (3p) is the most frequent site of non-random abnormalities in both hereditary and sporadic types[26,44]. A recent investigation by Kovacs *et al.*[45] has confirmed the high incidence of anomaly of chromosome 3, distal to band 3p11.2 or 3p13 manifested as a deletion. Restriction fragment length polymorphism analysis in patients with sporadic cancer of the kidney has shown loss of heterozygosity for one marker (D1S1) in 76 per cent of cases and for another marker (D3S2) in another 18 per cent of patients.

Conclusions

At present, the prevailing working hypothesis about oncogenes is that they are involved in the process of tumorigenesis as a result of a mutation which may directly affect their function as growth factors or may activate a growth factor gene. This would induce a state of autocrine stimulation of the cell and consequently its abnormal proliferation. On the other hand a mutation of a specific receptor for a growth factor may induce autostimulation and consequent prolonged cell division. Another possibility is that the cell may be stimulated by the abnormal functional behaviour of a cell receptor via a mediator released in the cytoplasm by a cell receptor for a growth factor.

Finally, as already mentioned, the concept of the anti-oncogene and its role in tumorigenesis should be kept in mind[35,46]. The gene product of the antioncogene may act normally to suppress cell division. When this gene or its gene product is inactivated, uncontrolled proliferation occurs.

Probably the process of tumorigenesis is more complex than this, and the main question to answer is: why should a deletion such as 13q14 in an embryonal retinal cell result in a retinoblastoma while the same deletion in another type of cell does not induce malignancy? One possible explanation is that random deletions occur frequently in many cells and in most cases they may be either tolerated or lethal, but in some cells the same deletion induces abnormal growth and thus cancer. Further investigation should elucidate the role that genetic predisposition to a certain type of cancer, together with environmental agents, may have in triggering the disease and whether prevention can be achieved in relatives of the patient. It has been suggested, for example, that cancer of the lung is due to the presence of an abnormal recessive gene on chromosome 3 and that the deletion observed in this type of tumour (3p21) involving the normal gene may be induced by tobacco smoking If this hypothesis turns out to be correct, patients at risk could be identified and preventive measures implemented. It is at this level of prevention that the close collaboration among oncologists, geneticists and surgeons is essential.

Dr J R. McGregor

Suture implantation of viable exfoliated malignant cells may be responsible for local recurrence (implantation metastasis) of colorectal cancer. In this study, four anastomotic materials (braided polyamide, braided polyglycolic acid, monofilament polypropylene and monofilament stainless steel) were compared with respect to their ability to entrap and transfer free Mtln3 carcinoma cells from the colonic lumen of a rat. The braided materials transferred greater numbers of cells than did the monofilament sutures ($P<0{\cdot}001$)*, but significant differences were also observed between polyglycolic acid and polyamide* ($P<0{\cdot}001$) *and between polypropylene and stainless steel* ($P<0{\cdot}05$)*. Secondly, the firm adherence of tumour cells to the suture materials was assessed by an* in vitro *technique. The Mtln3 cells were found to adhere in significantly greater quantities to the braided sutures than to the monofilaments* ($P<0{\cdot}001$) *and this was supported by* in vivo *tumour growth studies. These findings may have implications for colorectal cancer surgery in man.*

Keywords: Suture implantation, exfoliated malignant cells, local recurrence, colorectal cancer, implantation metastasis, braided sutures, monofilament sutures, adherence

Local recurrence is a major cause of morbidity and mortality following surgery for large bowel cancer. The reported incidence is variable[1–4], but a recent multicentre prospective study estimated the local recurrence rate to be approximately 14 per cent of patients who undergo ostensibly curative resection for colorectal cancer in the UK[5]. Around 80 per cent of cases present within the first 2 years of operation[3,6], and for the majority of patients no further 'curative' surgical intervention is feasible[7,8].

There is considerable clinical[9–11] and experimental evidence[12] to suggest that local recurrence may result from the surgical implantation of viable exfoliated malignant cells. Experimental studies have suggested that suture materials used to construct the anastomosis may have a part to play in this mechanism, a process frequently termed implantation metastasis. It has been shown that sutures are able to transfer malignant cells either from a solid tumour mass or from a cell suspension[13] in sufficient numbers to result in tumour growth in recipient animals, and that certain sutures can potentiate tumour growth when implanted into experimental animals with an inoculum of tumour cells[14]. Recent work has demonstrated that tumour cells differentially adhere to suture materials in a manner akin to bacterial adhesion[15].

This study was designed to assess the potential role of four anastomotic suture materials in implantation metastasis Two separate experiments were performed. The aim of the first was to compare the various materials with respect to their *in vivo* entrapment of free intraluminal tumour cells and the resultant transfer of these cells from the colonic lumen. The second experiment compared the extent of tumour cell adhesion to the same four materials, measured by an *in vitro* adhesion assay. *In vivo* tumour growth studies were also performed.

Materials and methods

Tumour cell line

The tumour used was the Mtln3 clone of the rat mammary adenocarcinoma 13762NF, cells of which were donated to the department by the originators of the clone, Drs Neri and Nicolson of the M D Anderson Hospital and Tumor Institute, Houston, Texas, USA The cells were cultured in either 75 cm^2 or 160 cm^2 tissue culture flasks (Nunc/Intermed, Kamstrup, Denmark) in medium consisting of equal parts of Hams's F10 and Dulbecco's modified Eagle's medium (F10/DMEM) with 10 per cent added fetal calf serum (FCS). Cultures were maintained at 37°C in an atmosphere of 2 per cent carbon dioxide in air and moved a maximum of six times between thawing and experimental use to minimize problems of phenotypic drift[16].

Suture materials

Four suture materials were tested. These comprised braided polyamide (Nurolon®, Ethicon Ltd., Edinburgh, UK), braided polyglycolic acid (Dexon Plus®, Davis and Geck, Gosport, UK), monofilament polypropylene (Prolene®, Ethicon Ltd.) and monofilament stainless steel (Ethicon Ltd), the latter being identical in composition to the material used in the manufacture of surgical staples Sutures of 5/0 gauge were used throughout.

Preparation of labelled cell suspension

A suspension of 10^7 Mtln3 cells per millilitre of F10/DMEM was prepared from near-confluent cultures. Cells were removed from the tissue culture flasks by treatment with Ca^{2+} and Mg^{2+} free phosphate buffered saline (PBS) followed by incubation for 10 min in 0 2 per cent trypsin (Gibco Ltd., Paisley, UK) at 37°C. An excess of F10/DMEM + 10 per cent FCS was then added to the culture flasks to neutralize trypsin activity, after which the cells were washed three times in this medium by centrifugation at 300*g* for 5 min and resuspension of the cell pellet Following the final resuspension, the cells were counted and the dilution adjusted Cell viability was ascertained by Trypan Blue exclusion and suspensions with over 95 per cent viabiltiy were obtained

Cells were then radiolabelled with ^{51}Cr which was obtained as sodium chromate ($Na_2{}^{51}CrO_4$) in minimal volume. A dose of 10 MBq of radiochromium was used per 10^7 tumour cells in a total volume of 4 ml. Labelling was carried out by incubation of the cell/^{51}Cr suspension for 90 min in a thermostatically regulated water-bath at 37°C with constant agitation Once incubation was complete, the tumour cells were washed four times in fresh RPMI 1640 + 10 per cent FCS medium (Flow Laboratories Ltd , Rickmansworth, UK) before counting of cell numbers and further assessment of viability. Finally the dilution was adjusted to produce a suspension of 10^7 viable labelled cells per millilitre of culture medium.

The in vivo *entrapment and transfer of tumour cells by sutures*

Twelve-week-old fasted male Fischer F344 rats were used throughout. Laparotomy was performed through a long midline incision and all residual faecal material was milked out of the caecum into the distal

10cm length of each suture passed transmurally
γ counter

Figure 1 In vivo *entrapment and transfer of Mtln3 cells in the wall of rat caecum*

colon Animals were then killed and immediately transferred to the radioisotope laboratory. An occlusive clamp was placed to isolate the upper caecal pole, into the lumen of which 0·1 ml of the radiolabelled tumour cell suspension was injected via a 24 gauge needle (*Figure 1*) A single 10-cm length of each of the four suture materials in turn was passed transmurally through this isolated, tumour-cell-containing segment, and the sutures were immediately transferred to the γ counter for measurement of radioactivity. Animals were used in groups of four or eight and the order in which the four types of suture were passed through the caecum was predetermined by a Latin square distribution which ensured that each suture was placed in each rank order once in every group of four animals (or twice in every group of eight)

The entire experiment was performed four times. twice with four animals and twice with eight For each assay the activity of a standard radiolabelled tumour cell suspension (10^6 labelled cells) was measured to allow calculation of the number of tumour cells adherent to the sutures. Background radioactive count was also measured and corrected for in the calculations.

The in vitro *adhesion of tumour cells to sutures*

Aliquots of 10^7 labelled tumour cells, each in 4 ml of F10/DMEM/FCS medium, were placed in four centrifuge tubes, one corresponding to each of the suture materials under test. Each tube received three separate 10-cm lengths of the appropriate suture material and the suspensions were incubated for 90 min at 37°C in the water-bath with constant agitation Each length of suture was then carefully removed with fine forceps and washed in PBS to remove any non-adherent cells This step was standardized by placing a beaker of PBS on a magnetic stirrer to produce a moving stream of PBS in which each length of suture was held for 15 s at a standard stirring speed and distance from the centre. Thereafter radioactivity was measured as before. This experiment was repeated four times in total and, as for the previous study, the radioactivity of standard labelled cell suspensions were used to calculate the number of cells that adhered

Controls

The above experiments were repeated using a cell-free solution of $Na_2{}^{51}CrO_4$ in culture medium instead of the radiolabelled tumour cell suspension. The purpose of this was to determine if any difference observed between the various suture materials reflected a difference in the number of tumour cells involved or whether it simply represented the attachment of non-cell bound chromium to the sutures

In vivo *tumour growth studies*

In the previous *in vivo* experiment the radioactivity levels of the sutures were measured within a very short period from the preparation of the cell suspension and so cell viability was assumed throughout. However, in the *in vitro* study, cell viability could not be assumed after the 90-min period of incubation To demonstrate tumour cell viability, lengths of each suture material were inserted transmurally into the caecum of 12-week-old male F344 rats after exposure to Mtln3 cells as described in the *in vitro* experiment The number of animals developing caecal tumours was recorded for each type of suture

Eight animals were used for each of the four anastomotic materials. Under ether anaesthesia, laparotomy was performed through a midline incision and five interrupted transmural sutures were placed in the upper caecal pole. All knots were tied loosely on the serosal surface and the abdominal incision was closed with continuous silk suture. Animals were killed on the 21st postoperative day and a full autopsy was performed The procedure was later repeated with a further 24 animals, six per suture material, and on this occasion groups of rats were only killed when the animals were visibly unwell or when two or more members of the group had died

Statistical methods

For the *in vivo* and *in vitro* experiments an overall statistical assessment was made using the Kruskal–Wallis test. Comparisons between individual suture materials were made using the Mann–Whitney U test Results for the *in vivo* tumour growth studies were compared using Fisher's exact test

Results

Tumour cell entrapment and transfer in vivo

Both the braided suture materials and, in particular, polyglycolic acid transferred significantly greater numbers of tumour cells from the caecal lumen than did either monofilament stainless steel or monofilament polypropylene ($P<0{\cdot}001$; Mann–Whitney U test) (*Table 1*). Polyglycolic acid transferred a significantly greater number of tumour cells than polyamide ($P<0{\cdot}001$). The number of cells transferred by polypropylene was significantly greater than the number transferred by stainless steel ($P<0{\cdot}05$). The median numbers of Mtln3 cells transferred per suture for each material are illustrated diagrammatically in *Figure 2.*

Tumour cells adherence in vitro

The Mtln3 tumour cells firmly adhered in significantly greater numbers to the two braided suture cells than they did to either of

the monofilaments (*Table 2* and *Figure 3*). Despite the very wide range of values recorded these differences between the braids and monofilaments were highly significant statistically ($P < 0{\cdot}001$) However, in this experiment polyglycolic acid and polyamide could not be separated statistically nor could stainless steel and polypropylene.

Results using free ^{51}Cr

There were no significant differences between the various suture materials with respect to the measured radioactivity levels when either of the experiments was performed using the solution of free ^{51}Cr. The results are expressed in *Table 3* as medians and ranges.

Animal controls

Of the first group of 32 animals killed on the 21st postoperative day, 19 had macroscopic tumours of the upper caecal pole. No histological abnormalities were seen in the 13 macroscopically normal animals apart from a variable acute inflammatory infiltrate. The distribution of the animals developing tumours according to the type of suture material was as listed in *Table 4*.

When the experiment was repeated with the group of 24 rats in which killing was delayed, only two animals (one with stainless steel suture, one with a polypropylene suture) were found to be tumour free at autopsy. The remainder all had macroscopic evidence of intra-abdominal tumour although the time from surgery until the animals were visibly unwell did appear to correlate with the type of suture material. Two of the animals with polyglycolic acid sutures died on day 26 and the group was therefore killed on that day. The group with polyamide sutures was also sick by this time and was similarly killed. The group with stainless steel sutures remained healthy until day 33 when two of the rats were noted to be unwell whereas the group with polypropylene sutures did not reach this stage until day 36.

Discussion

In recent years there has been little change in the long-term prognosis following 'curative' resection of colorectal cancer. The overall 5-year survival of such patients treated in specialist institutions remains around 50–60 per cent[2,17] and the incidence of local recurrence is a major factor limiting improvements in this figure. As this clearly represents a local failure of surgical management, the relationship between surgical technique and local recurrence merits further investigation, particularly in the light of some recent reports suggesting a possible association

between stapled colorectal anastomoses and an enhanced risk of local recurrence[18,19].

In 1885, Gerster proposed that the mechanical dissemination of tumour cells at operation might be responsible for local recurrence[20]. Support for this hypothesis came when McGrew *et al* demonstrated malignant cells in Papanicolaou smears taken from both the proximal and distal resection margins of colonic cancer resection specimens[21]. Rygick *et al.* reported similar findings in smears taken from surgical instruments and from the surgeon's gloves[22] Although the viability of these exfoliated cells, and hence their ability to give rise to recurrent tumour, was subsequently questioned by Rosenberg *et al.*[23], it has recently been demonstrated that viable tumour cells are present in large numbers in the colonic lumen of patients with colorectal cancer[10].

Free tumour cells are incapable of implanting on normal colonic mucosa but they will readily grow on serosal and peritoneal surfaces[24]. While the divided bowel ends at an anastomosis, with their exposed serosa and raw muscle edges, obviously present a fertile field for tumour cell implantation, the suture material used to construct the anastomosis may also have a part to play The implantation of tumour cells by suture materials has been described in animal models[12,13] and it has been demonstrated that the use of iodized sutures effectively decreases the incidence of tumour development in such experimental studies[25,26]. Suture materials may be further implicated in implantation metastasis in that they may act as a nidus for the adherence of tumour cells once they have been implanted into the colonic wall[15].

In this study we have shown that, of the anastomotic materials tested, the two braided sutures were able to entrap and transfer significantly greater numbers of free intraluminal tumour cells *in vivo* than were either of the monofilament materials ($P<0{\cdot}001$). The results from the *in vitro* study suggest that the braided sutures have a greater propensity to act as a nidus for implanted malignant cells since the tumour cells adhered in significantly greater numbers to them than they did to the monofilaments. The animal studies served to illustrate the highly malignant nature of the tumour cell line used in these experiments and the persistent viability of Mtln3 cells incubated *in vitro* with ^{51}Cr for 90 min. The differences recorded in tumour growth correlated precisely with the rank order in which the *in vitro* study placed the adhesion of tumour cells to each suture material.

We conclude that the choice of anastomotic suture material may have an important influence on the risk of implantation metastasis. Should this mechanism apply to colorectal cancer surgery in man, then our results would suggest that monofilament suture materials may be associated with a lesser risk of local recurrence than are braided materials. However, the significant differences between polyamide and polyglycolic acid and between polypropylene and stainless steel with respect to the *in vivo* entrapment and transfer of tumour cells suggest that the composition of a suture material is important in addition to its physical characteristics. Further investigation of a variety of commonly used anastomotic suture materials is therefore warranted as part of the continuing search for ways of reducing the incidence of local recurrence after apparently curative surgery for large bowel cancer

This study attempts to define whether there is an increased need for reoperation in patients with small bowel Crohn's disease treated by strictureplasty compared with those treated by small bowel resection. Previous studies of the rate of reoperation for small bowel Crohn's disease do not distinguish between reoperation performed because of a lesion at the original operation site and that undertaken because of a lesion at a distant site. This study analyses the need for reoperation only at the original site of operation and measures operation-free intervals. The site specific operation-free intervals in 41 patients with small bowel Crohn's disease treated by strictureplasty were not significantly different from the similar intervals in 41 patients treated by a small bowel resection.

Keywords: Crohn's disease, strictureplasty and resection for Crohn's disease, reoperation for Crohn's disease

Over the past decade, strictureplasty has become a useful technique in the surgical management of strictures in small bowel Crohn's disease[1]. Although an intestinal resection is the operation of choice for the common presentation of Crohn's disease confined to the ileocaecal region[2–4], strictureplasty is a convenient, simple and safe technique when the distribution of the disease makes multiple resections impractical, as in patients with multiple short areas of small bowel Crohn's disease.

Resection involves removal of the macroscopically diseased bowel whereas with strictureplasty the diseased bowel remains. Therefore it is possible that recrudescence of symptomatic Crohn's disease at the site of operation might occur earlier following strictureplasty than following resection. Many studies record the incidence of reoperation in patients who have previously undergone surgery for small bowel Crohn's disease[2–8] but they do not differentiate between recrudescence of disease at the original site of operation and recrudescence at sites distant from the site of previous surgery.

To assess the efficacy of strictureplasty in the management of individual strictures it is necessary to consider the need for reoperation at the site of the original stenosis rather than that carried out because of recrudescence of disease at other sites.

Patients and methods

A retrospective analysis was made of the case records of two groups of patients that had undergone surgery at the General Hospital, Birmingham for Crohn's disease of the small bowel.

Group A consisted of 41 patients in whom the disease had been treated by resection only. Group B consisted of another 41 patients in whom the disease had been treated at least once by strictureplasty; 36 patients in this group had also undergone at least one bowel resection for Crohn's disease. The two groups of patients were well matched for age, sex and the length of follow-up (*Table 1*). When combined, the two groups comprised 82 patients who had undergone a total of 174 small bowel resections and 129 strictureplasties (*Table 2*).

Our analysis was concerned with individual sites of disease within patients and, in particular, with the times between procedures at each site, which we refer to as 'reoperation-free intervals'. We studied 44 separate sites in the 41 patients of group A and 136 sites in the 41 patients of group B. For patients who had undergone surgery at more than one site, there was clear documentation which enabled us to distinguish reoperation-free intervals for each site separately.

Statistical analyses

Statistical comparisons between rates of reoperation following resections and strictureplasties are limited by the fact that strictureplasty has only been used widely in our hospital since 1981, whereas the records for resections go back for more than 40 years. Many patients treated by strictureplasty are still under 'open follow-up' (no reoperation yet required) and so we have only censored estimates of the intervals (i.e. lower limits on the final values of these intervals). In contrast, we have more completed intervals for the time to reoperation following resection and have longer periods of open follow-up. As a result, we are cautious about comparisons between the two procedures beyond the first few years after each operation. Our sample included 26 patients who had undergone at least two resections at the same site: eight of each sex from group A and five of each sex from group B. The coefficient of correlation between their first and second reoperation-free intervals was only 0·25 and a Wilcoxon signed rank test showed that there was no significant difference between the mean first and second intervals ($P = 0·052$), so we subsequently treated all intervals as independent and homogeneous.

The apparent multiplicity of sites amongst the patients who had undergone resection (41 of group A and 36 of group B) is caused almost entirely by these patients having received successive resections at a single site. Only two patients (one man and one woman, both in group B) recorded completed post-resection intervals at a second site, seven others recorded censored intervals at only one additional site, and one recorded censored intervals at two additional sites.

Because most of the strictureplasty sites are still under open follow-up, we have little information about the joint distribution of intervals after this procedure at different sites in the same patient. However, we see no reason to suppose that the correlation would be greater than that between successive intervals at the same site after resection.

The percentage of sites free of reoperation as a function of time in months was calculated by the Kaplan–Meier technique[9], which is especially suitable for relatively small samples and takes account of censoring (patients still under open follow-up). This technique was used to prepare *Figures 1* and *2*.

Table 1 *Details of 82 patients who had undergone operation for Crohn's disease of the small bowel*

Group	Mean age (years)	No. of patients (F:M)	Mean follow-up from first operation (years)
Group A			
Resection only ($n = 41$)	45 (25–85)	26·15	17·4 (1–39)
Group B			
Strictureplasty* ($n = 41$)	44 (20–76)	25:16	15·2 (1–45)

Ranges are given in parentheses, * 36 patients in this group had also undergone at least one bowel resection for Crohn's disease

Table 2 *Procedures carried out in 82 patients who had undergone surgery for Crohn's disease of the small bowel*

Procedures	Group A ($n = 41$)	Group B ($n = 41$)	Total
Strictureplasties	—	129	129
Resections	93	81	174

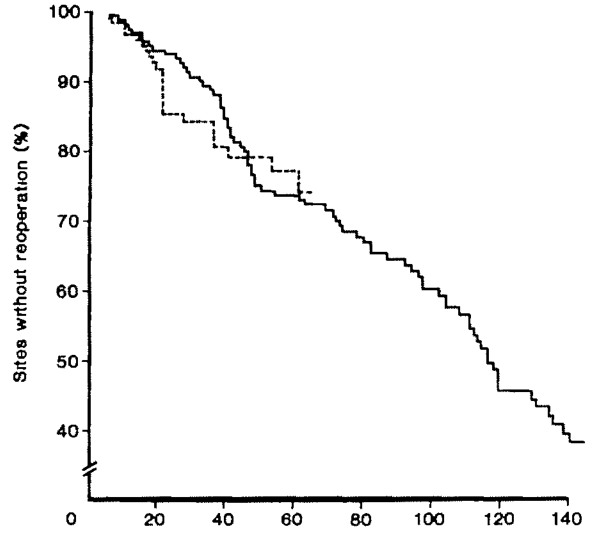
The log rank test[10] was used to check for significant differences between the Kaplan–Meier estimates for resections in groups A and B which are shown in *Figure 2* Because of the discrepancy in the lengths of follow-up, this test was not appropriate for comparing resections with strictureplasties (*Figure 1*) However, approximate standard errors for each curve were calculated by the method of Peto *et al* [10] (*Table 3*) and these were used for a rough check on differences between the curves



NO. OF SITES AT RISK								
Resections	173	153	126	103	87	68	44	30

Figure 1 *Percentages of sites without reoperation* ——, *resection (groups A and B combined),* – – –, *strictureplasty (group B) (Kaplan–Meier estimates) The number of sites at risk are shown*

Sharp falls in the Kaplan–Meier curves indicate periods of increased risk of reoperation. This is best measured by the hazard rate[11] which represents the percentage of sites that remain unstrictured for the time to which the rate refers, then require reoperation shortly afterwards To obtain estimates of hazard rates in *Figures 3* and *4* we used the life table method[11] with 10-month intervals. Standard errors of these estimates are given in *Table 4*

Results

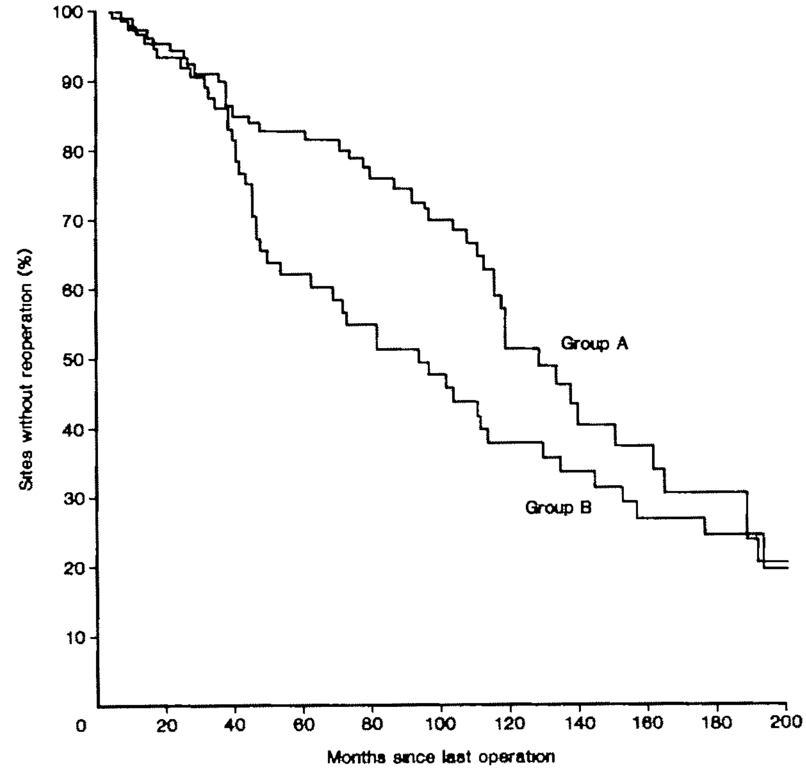
For the 60 months over which comparisons can be made, the Kaplan–Meier estimates indicate that there is no significant difference between the percentages of sites without reoperation after resection and the corresponding percentages after strictureplasty. The visual impression of *Figure 1* is reinforced by comparing the standard errors in *Table 3*, where it can be seen that the one-standard-error bands on either side of each curve always overlap.

The corresponding hazard rates are shown in *Figure 3*, where the resections exhibit two marked peaks, an early one (at about 40 months) and a late one (at about 110 months). Between these peaks, the hazard rate hovers around 0·5 per cent per month, i.e.

Table 3 *Kaplan–Meier estimates of percentages of sites without reoperation*

	Procedures	
Months	Resections (groups A and B)	Strictureplasty (group B)
20	94·6 (±1·8)	91·9 (±2·5)
40	83·5 (±3·0)	79·1 (±5·1)
60	73·9 (±3·7)	74·3 (±7·4)

Values are mean percentages with standard errors in parentheses



SITES AT RISK

6 per cent per annum. *Table 4* shows that these peaks clearly lie outside the one-standard-error limits of the other hazard rates. As the standard errors are only approximate, we also carried out a further check to find whether the underlying hazard rate for all resections was constant from 4 to 150 months.

Considering all complete and randomly censored observations up to 150 months and the number of survivors at 150 months, we found that the maximum likelihood estimate of such a constant rate would be 0·57 per cent per month. A likelihood ratio test using the numbers of complete and censored observations in each of the 15 intervals then showed that our data were not compatible with this constant hazard rate hypothesis ($\chi^2 = 33{\cdot}5$, d.f. between 14 and 15, $P < 0{\cdot}005$). The choice of a 150-month horizon is arbitrary, but this test confirms our belief in the reality of the peaks. There is also a suggestion of a peak at about 20 months on the graph of the strictureplasty hazard rate (*Figure 4*). This may represent a forward shift in the restricturing time represented by the 40-month peak for resections (*Figure 3*). The minimum observed interval between operations was 5 months for both procedures. To allow for the possibility of a slightly shorter interval, the hazard rates for the first 10 months were calculated on the assumption that the minimum possible interval was 4 months (*Figures 3* and *4*).

Before combining the results for all the resections to obtain the Kaplan–Meier curve in *Figure 1*, we had analysed separately those performed alone (group A) as well as those performed in combination with strictureplasty (group B) as shown in *Figure 2*. Despite the visual difference between the two curves the log rank test showed that, overall, there is no significant

100	0·49 (±0·34)	0·85 (±0·58)	0·63 (±0·31)	
110	2·54 (±0·78)	1·46 (±0·78)	2·12 (±0·57)	
120	0·47 (±0·46)	0·00 (±0·00)	0·25 (±0·25)	
130	1·21 (±0·80)	1·21 (±0·80)	1·21 (±0·57)	
140	0·71 (±0·68)	0·69 (±0·67)	0·70 (±0·48)	

Values are mean monthly hazard rates as percentages with the standard error in parentheses difference between them ($\chi^2=2.19$, $P=0.14$) However, this test is not specifically concerned with peaks in the hazard rates In *Figure 4* it can be seen that the reoperation hazard rate in patients having had resections alone and in those having resection combined with strictureplasty make different contributions to the early and late peaks. The early peak is made up almost entirely of contributions from the patients undergoing resections combined with strictureplasty (group B). The larger part of the later peak comes from those having resection alone (group A).

Discussion

In this study no significant difference was found in operation-free intervals following resections or strictureplasties for obstructive small bowel Crohn's disease. Statistically valid comparisons could be made for the first 60 months only, owing to the recent introduction of strictureplasty (*Figure 1*) Nevertheless, this finding seems to support the claim that remaining disease does not precipitate early recrudescence at the operated site[8,12].

Since 1971 several authors have presented 'circumstantial' evidence suggesting the possibility that two clinical forms of Crohn's disease might exist: an 'aggressive' form of the disease has a tendency to higher recurrence rates, more extensive involvement, and more abscess and fistula formation, while the other form is characterized by a more quiescent clinical course. This hypothesis was based on observations concerning the relationship between the duration of the disease before the initial operation and the subsequent reoperation rate Correlation between types of indications and recurrence rates has also been demonstrated and several studies have shown biphasic cumulative curves of recurrence (early and late reoperations)[5–8,13]. Our findings seem to support this view in that the reoperation rates following resections clearly show two peaks (*Figure 3*) at 40 and 110 months. When the hazard rates were calculated separately for each group (*Figure 4*), the peaks were still present. However, the interesting point that emerged was that the early peak was composed almost exclusively of contributions from resections in group B patients (strictureplasty, some with resection), whereas the major component of the late peak was from group A patients (resections only) This early peak of reoperation hazard rate in the group of patients who had more extensive and multifocal disease (as most of them required multiple strictureplasties and simultaneous resections) might represent the more aggressive form of disease However, identification of the two peaks on the hazard rate with separate forms of the disease must remain speculative until further data become available.

The minimal interval between reoperations was 5 months for both procedures. As the intervals refer to specific sites only, it is interesting to note that there might be a minimal 'restricturing time' which is similar regardless of whether the diseased segment is excised or left *in situ*.

In conclusion, strictureplasty appears to be an alternative to wide or multiple resections for multifocal stenotic small bowel Crohn's disease. It is indicated particularly in those patients in whom multiple short segments are involved and obstructive symptoms are present. Whether function of the preserved bowel is worthwhile, or whether this bowel carries an increased risk of malignancy (as appears to follow bypass procedures) remains unknown.

Mr T. C B Dehn, Department of Surgery, John Radcliffe Hospital, Headington, Oxford OX3 9DU, UK

Strictureplasty is controversial in the management of obstructive Crohn's disease. Only a small proportion of patients undergoing surgery for obstructive Crohn's disease are suitable for strictureplasty. Lesions which are most amenable for this procedure are short, fibrous strictures. Over a 10-year period 24 patients have undergone 30 operations at which 86 strictureplasties were performed. The median follow-up has been 40 (range 4–112) months. No leaks or fistulae arose from the strictureplasties. The median weight gain 3 months postoperatively was +4·0 kg. Four patients subsequently required a further 13 strictureplasty procedures, between 12 and 36 (median 18) months after the initial operation; all but one of the previous strictureplasties were patent. Thirteen patients have been symptom free following surgery, four have required further medical therapy for recurrent Crohn's disease and three have sustained episodes of self-limiting intestinal colic. Strictureplasty is a safe and effective procedure in selected patients undergoing surgery for obstructive Crohn's disease.

Keywords: Crohn's disease, intestinal obstruction, minimal surgery, strictureplasty

Approximately one-third of patients with Crohn's disease will require repeated surgery for recurrent disease[1,2]. One of the risks of repeated or extensive resection is malnutrition due to the short bowel syndrome.

The concept of minimal surgery for Crohn's disease[3–5] has been gaining acceptance and, in particular, the operation of strictureplasty is being more widely used. The technical aspects of the operation are controversial as not only does overtly diseased intestine remain unresected, but also the anastomosis is made through macroscopically affected bowel. Sceptics have feared a high rate of both fistulae and early relapse of Crohn's disease following this surgery.

This paper reports this unit's 10-year experience.

Patients and methods

Between 1 January 1978 and 1 January 1988, 24 patients (10 men, 14 women, median age 33 years, range 17–45 years) underwent 30 strictureplasty operations Patients were reviewed in the outpatient department ($n = 19$), and those living abroad were contacted by letter ($n = 5$).

The criteria for patients with obstructive Crohn's disease to be selected for possible strictureplasty were the presence of symptoms unresponsive to medical therapy and intestinal strictures on small bowel enema. At laparotomy all sites of macroscopic Crohn's disease were inspected; the following factors were those which influenced the decision to undertake strictureplasty in preference to excision of the affected obstructed segment: (1) length of remaining intestine, (2) length of affected segment, (3) inflammatory activity of affected segment, and (4) proximity of other affected segments.

Results

Eighty-six strictureplasties were performed at 30 operations. The median follow-up is 40 (range 4–112) months.

Prior history of Crohn's disease

Crohn's disease had been diagnosed for a median 72 (range 0–240) months In nine patients this diagnosis had been present for >10 years. Seventeen patients had, before strictureplasty, undergone 36 operations for Crohn's disease (25 small bowel resections, six right hemicolectomy and terminal ileal resections, two proctocolectomies, two gastroenterostomies, one split ileostomy).

Preoperative details

Obstructive symptoms had been present for a median of 4 (range 1–240) weeks. Intestinal Crohn's disease strictures were identified preoperatively by small bowel enema in 26 of 30 instances (87 per cent). Barium enema demonstrated ileocolic anastomotic strictures in two cases, plain X-ray demonstrated intestinal obstruction in one case and one patient underwent emergency laparotomy. The following nutritional and disease activity indices were recorded preoperatively (figures are median and range): weight 51 (32–76) kg; Hb 11·3 (10–14·4) g/100 ml; albumin 34 (18–43) g/l; and erythrocyte sedimentation rate 24 (3–64) mm/h.

Operative details

All patients received 5 days of intravenous cephalosporin and metronidazole and all but one patient received perioperative steroid therapy. Strictures were identified in 22 operations by the passage at enterotomy of a 36 Fr plastic oesophageal tube (external diameter 12 mm) and in the remaining eight by perenterotomy pull-through of a 20 Fr Foley balloon catheter, inflated with 3 ml of saline giving a balloon diameter of 2 cm (Reference 6).

Eighty-six strictureplasties were performed: 80 were jejunoileal, four at the site of previous ileocolic anastomoses, one at the duodenal–jejunal junction and one at the site of a previous strictureplasty; 78 were closed in the manner of Heinecke-Mickulicz, and eight similar to that of Finney. Anastomosis was by continuous one-layer 3/0 Vicryl® (Ethicon Ltd., Edinburgh, UK) or two-layer continuous 3/0 chromic catgut. The median length of the strictureplasty was 3 (range 1–17) cm. The number of patients having single or multiple strictureplasties was as follows: one procedure in 15 patients, two procedures in five patients, three in three patients, four in three patients, six in two patients, seven in one patient, and 21 in one patient Simultaneous intestinal resections were undertaken in 15 patients (12 jejunal–ileal resections, three ileocaecal resections).

Early postoperative (0–30 days) results

There were no deaths, fistulae or wound infections related to the operative site. One patient developed an intra-abdominal abscess and subsequent duodenocutaneous fistula from a missed duodenojejunal fistula. Parenteral nutrition was given post-

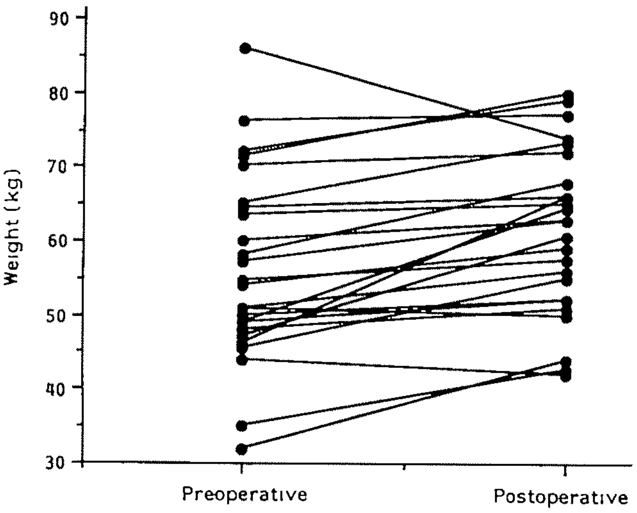

Figure 1 *Diagram illustrating preoperative and postoperative weights (kg) at 3 months recorded after 26 strictureplasty operations*

operatively to 23 of 30 (77 per cent) patients for a median of 7 (range 5–18) days. The median time between operation and discharge was 12 (range 7–23) days.

Long-term postoperative results

The median weight gain recorded 3 months postoperatively was +4·0 (range from −12 to +20) kg ($t = 3{\cdot}13$, $P < 0{\cdot}01$, *Figure 1*). The marked postoperative weight loss (−12 kg) recorded in one patient was secondary to a reduction in preoperative steroid-induced weight gain These weight changes have persisted over subsequent follow-up

Recurrent operations

Four patients have undergone a total of ten operations for further obstructive symptoms (two patients had two operations and two patients had three operations) at 18 (range 12–36) months after their previous strictureplasty Thirteen further strictureplasties were performed. All but one of the previous strictureplasty sites were found to be patent and were not the cause of the obstruction One patient in this group underwent laparotomy for adhesive small bowel obstruction 1 month after her third strictureplasty operation and has been symptom-free thereafter

Of the remaining 20 patients, 13 have been symptom-free following strictureplasty, one requiring division of adhesive small bowel obstruction, 5 years after strictureplasty surgery Three patients have suffered minor attacks of self-limiting colicky abdominal pain and four patients have required a total of six hospital admissions for further medical therapy of recurrent Crohn's disease.

Discussion

The majority of patients with Crohn's disease will undergo surgery during the course of their disease[7,8]. Greenstein *et al.*[9] demonstrated that not only does the rate of recurrence increase with the length of follow-up but also there is a group of Crohn's disease patients who require repeated resections at increasingly frequent intervals. This group is at the greatest risk of developing malnutrition secondary to surgically induced short bowel syndrome[4]. Hellers[2] reported a 1·5 per cent incidence of this syndrome in his series of 102 patients and the Leeds study[1] reported a postoperative weight loss of >12·7 kg in 5 1 per cent of 198 patients undergoing resection for Crohn's disease

The principle of minimal surgery for Crohn's disease is that surgery should be structured to improve both the health and symptoms of the patient, while preserving as much intestine as possible[3,4]. This concept of preserving intestine is based on the understanding that, firstly, Crohn's disease is microscopically pan-intestinal; secondly, once diagnosed the patient is always at risk of relapsing; and, thirdly, recurrence of Crohn's disease has been demonstrated to be independent of the presence of microscopical disease at intestinal resection margins[10,11]. Furthermore, no successful adjuvant medical therapy has been shown to decrease the incidence of recurrence following surgery.

The technique of strictureplasty invited criticism as not only does diseased bowel remain *in situ*, but also the anastomosis is constructed through macroscopically involved intestine. The use of this operation can only be justified if the results prove the procedure to be safe, to improve the health of the patient and to be no worse than conventional excisional surgery.

The patients in this series comprised those with malnourishment (>20 per cent weight loss, serum albumin <30 g/100 ml), those with high activity indices of Crohn's disease, those who required intravenous nutrition and high dose steroid therapy, and those patients who were able to maintain normal bodyweight and nutrition in the presence of colicky abdominal pain.

The fears of early postoperative abscess formation and fistulae following this surgery have proved groundless, despite the facts that in two patients the operation was undertaken through segments exhibiting acute disease and that seven patients had between four and 21 strictureplasties fashioned at one operation.

Furthermore, the long-term benefits of strictureplasty surgery are confirmed by our study as continued nutritional and symptomatic improvement has been maintained in 20 of 24 patients It is interesting that the sites of recurrent obstructive Crohn's disease do not appear to occur in segments of bowel on which a strictureplasty has been previously performed, as illustrated by the four patients in our series who have undergone further surgery.

Other surgeons who have performed this operation for obstructive Crohn's disease have also reported encouraging results[12–15]. Alexander-Williams[12] has performed 148 procedures in 52 patients, 29 of whom had undergone previous excisional surgery. four anastomotic leaks were reported and 60 per cent of patients had an excellent clinical result 6 months postoperatively. However, Kendall *et al.*[16], have reported recurrence of pain in seven of nine patients, four of whom required further laparotomy, and, in three of these cases, further strictureplasties were undertaken The early recurrence of obstructive symptoms following strictureplasty reported in that series was not thought to be because of recurrent disease in strictureplastied bowel[16].

Strictureplasty should be used in conjunction with conventional excisional surgery At Oxford, the annual number of operations performed for Crohn's disease is between 32 and 40. Since its introduction to our unit strictureplasty is performed approximately three times per annum. Thus, we stress the importance of careful operative selection of the lesions most likely to respond well to strictureplasty. Distinction must be made between segments of bowel obstructed either by phlegmonatous Crohn's disease or by fibrotic Crohn's disease. We believe that the former lesions are best treated by 'mini resection'[4] and that if treated by strictureplasty they may well be the site and cause of early postoperative recurrence of symptoms, while the latter lesions are those most amenable to strictureplasty Adherence to these principles has permitted us to undertake strictureplasty in patients with both limited and extensive disease

Whether this operation is as effective, in the long term, as resection of bowel affected by Crohn's disease, remains unanswered. We do not claim that our good results are entirely consequent on strictureplasty since 15 patients underwent simultaneous resections. Nevertheless, we believe that our results demonstrate the procedure to be safe, in particular, with respect to anastomotic failure and fistula formation, we found it to be an effective means of preserving intestine and relieving obstructive symptoms.

We recommend its use, in conjunction with conventional excisional surgery, for patients with obstructive Crohn's disease, and we stress the importance of ensuring that no distal obstruction remains unrelieved for fear of precipitating anastomotic dehiscence at the site of strictureplasty[12,16].

Associate Editor

Mr A. E. Young is relinquishing his appointment as Associate Editor of the Journal this month and the increasing workload of the post is reflected in the fact that he will be replaced by not one but two Associate Editors, Professor John Farndon from Bristol and Mr John Murie from Edinburgh.

Tony Young joined the editorial team of *The British Journal of Surgery* partly for his literary and editorial skills, which are considerable, and also to give aid in the birth of our computerized office; the delivery of this latter infant was not without its setbacks, but it is now thriving and we are deeply grateful to Tony for his hard work and common sense during this difficult time. He will not be severing his links with *The British Journal of Surgery* but will remain a member of the Editorial Committee.

T tubes: a comparison of virgin, slit, guttered and sculpted design

L. Crnojevic*, J. N. Thompson and
H. A. F. Dudley

*Academic Surgical Unit, St Mary's Hospital, London W2, UK and *Department of Surgery, Army Hospital, Pula, Yugoslavia*

T tube drainage after supraduodenal bile duct exploration remains common practice[1–3], although the general pattern of T tubes commonly used today was first described by Deaver in 1904[4]. Although uncommon, bile peritonitis is a well-recognized event after T tube removal. Corbett *et al.*[5] estimated the incidence following removal of latex T tubes to be 1 in 119 patients. Extrapolated to the UK, such an incidence would imply approximately 50 cases each year, with their attendant morbidity and mortality.

A number of factors have been implicated in the development of bile peritonitis after T tube removal[5–8], including inadequate track formation, the choledochotomy suture technique, technical errors, distal bile duct obstruction and the type of T tube material used. While these and other factors may be important, it is our hypothesis that the force required for T tube removal is the major factor determining whether the bile duct or T tube track is disrupted with consequent bile leakage and peritonitis.

Surgeons vary in the size and design of T tubes they use and also in the surgical modifications they make to commercially available latex rubber T tubes. The aim of this study was to assess the factors influencing the force required for T tube removal, particularly the effect of surgical T tube modification.

Methods

To measure the force required for T tube removal an *in vitro* model was used. Latex rubber Kehr T tubes supplied by Warne Surgical Products, Andover, UK were pulled through circular holes of varying size in a rigid plastic sheet 0·5 mm in thickness. The force on each T tube was gradually increased until the tube was completely pulled through the hole. The maximum force required was measured using a spring balance. For each experiment five T tubes of each size and design were used.

The effect of T tube design

For this study, 16 French gauge (Fr) T tubes with side arms each of 2·5 cm in length were used. Four designs of T tube were studied: virgin (unmodified), slit (side arms cut along their length), guttered (half the circumference of the side arms removed), and sculpted (guttered with two Vs cut out opposite the main stem of the T tube) (*Figure 1*). The tubes were pulled through holes ranging in size from 16 to 30 Fr.

The effect of T tube size

T tubes of size 12, 14, 16, 18 and 20 Fr and of each design (virgin, slit, guttered or sculpted) were used. In each case the tubes were pulled through holes of the same size.

The effect of side-arm length

This was studied using virgin 16 Fr T tubes pulled through holes of 16, 18, 20 and 30 Fr. The force required was measured at each hole size for tubes with side arms ranging from 1 to 5 cm in length.

Results

The effect of T tube design

The effect of T tube design is shown in *Figure 2*. The differences between each design of T tube were significant at the 5 per cent level for all hole sizes using unpaired *t* tests. At all hole sizes, sculpted tubes required approximately 10 per cent of the force needed for virgin tubes.

The effect of T tube size

There was a progressive reduction in the force required for T tube removal with diminution in the size of the T tube (*Figure 3*). This reduction was seen with all four designs of T tube. A reduction in the size of the T tube by 2 Fr significantly reduced the force required for tube removal in 11 of the 16 direct comparisons made in this experiment ($P < 0{\cdot}05$, unpaired *t* tests).

The effect of side-arm length

There was no significant difference in the maximum force required to remove 16 Fr T tubes through holes of 16, 18, 20 and 30 Fr as the side-arm length was reduced by 1 cm lengths from 5 cm to 1 cm.

Discussion

When considering the complication of bile peritonitis following T tube removal, surgeons have largely focused their attention on the tissue reaction to different materials from which T tubes have been made. It has been held that inflammation is desirable to the formation of a tight sinus track which will prevent leakage at the time of withdrawal. This hypothesis has been used to explain the fact that shortly after the introduction of polyvinyl chloride T tubes, which produce less tissue reaction, several authors reported diffuse bile peritonitis[6,9].

The continued occurrence of biliary peritonitis following removal of latex T tubes[5,7,8] suggests that other factors also play a part. Although this complication probably has a multifactorial aetiology, it would seem reasonable to assume that excessive force should be avoided during T tube removal so that the risk of disruption of the common bile duct or established T tube track is minimized. The present study did not simulate the exact conditions existing during removal of T tubes from patients: the elasticity of the common bile duct differs from the plastic material used, the hole in the common duct may be elliptical rather than circular, and there was no bile to lubricate the T tube. Despite these differences this study shows that the major mechanical obstacle to T tube removal is located at the junction of the side arms with the main stem, and that the resistance to removal caused by this junction is altered substantially *in vitro* by the modifications in T tube design assessed in this study. The sculpted tube effectively eliminates the resistance caused by the junction of the T tube.

The suggestion by radiologists that a large diameter T tube should be used routinely after bile duct exploration to facilitate the later percutaneous extraction of any retained stones should be considered cautiously by surgeons as the larger T tubes required increased force for their removal.

We suggest that to minimize the risk of bile peritonitis after T tube removal, surgeons should opt for a smaller size of T tube where appropriate and, perhaps more importantly, should sculpt their T tubes before placing them in the common bile duct. In addition, the removal of all T tubes should be undertaken with care. It is anticipated that such steps would substantially reduce the continuing surgical morbidity and mortality related to the use of T tubes.

Sutureless colonic anastomosis using a biofragmentable anastomosis ring (BAR) has been evaluated in a prospective randomized comparison with sutures and staples for elective colorectal surgery. One hundred and one patients underwent BAR anastomosis, 85 a sutured anastomosis, and 16 a stapled anastomosis. There were two anastomotic leaks in the patients undergoing BAR anastomosis, seven in patients having a sutured anastomosis, and one in a patient who had a stapled anastomosis. Wound infection occurred in ten BAR patients, ten sutured patients and no stapled patient. There was no statistically significant difference in these or in other postoperative complications between the groups. The BAR was easy to use and is a safe alternative to sutures and staples for large bowel anastomosis.

Keywords: Colon surgery, surgical staples

A significant part of the morbidity and mortality associated with colonic anastomosis results from anastomotic leakage, and surgeons are constantly seeking to improve anastomotic techniques.

Nicholas Senn of Chicago wrote in 1893: 'We have reason to believe that the technique of intestinal suturing remains an unfinished chapter, and that the ideal method of uniting intestinal wounds has yet to be devised'[1]. A technique of sutureless anastomosis was conceived by Denans in Marseilles in 1826[2] which encompassed the inverting technique proposed by Antoine Lembert[3]. However, it was not until 1892 that Murphy designed a 'button' that gained more widespread acceptance[4] (*Figure 1*) This, too, fell from favour because it relied on necrosis for its release from the anastomotic site, and not infrequently it became impacted lower down the gastrointestinal tract. Senn[1] summarized the criteria for a successful sutureless anastomotic device thus: 'Any internal aids to circular suturing should be composed of absorbable material and employed in such a way as not to produce marginal gangrene and with a central opening large enough to allow free faecal circulation'. A bowel anastomosis ring seeking to fulfil these criteria has been devised by Hardy *et al.*[5], and produced by Davis and Geck (Valtrac®; Danbury, Connecticut, USA). This device has been evaluated in a European multicentre prospective randomized trial comparing it with sutured and stapled anastomoses.

Patients and methods

The Valtrac anastomosis ring (BAR) is a biofragmentable device composed of polyglycolic acid polymer and 12·5 per cent barium sulphate. γ-Irradiation both sterilizes the device and facilitates its disintegration at the appropriate time of 16–23 days, barium renders it radio-opaque. It constructs a secure inverting anastomosis with accurate serosa-to-serosa apposition until healing occurs The device then fragments and soft pieces are passed out in the stool.

The device is supplied in 28, 31 and 34 mm external diameter sizes, with a 6 mm open gap-width (*Figure 2*) Closed gap-widths of 1·5 and 2·0 mm are available for the 28 and 31 mm sizes, and closed gap-widths of 2·0 and 2·5 mm are available for the 34 mm diameter BAR to accommodate different thicknesses of bowel wall. A monofilament absorbable purse-string or whip stitch is inserted into the bowel ends to be joined using a modified purse-string instrument (Davis and Geck) or by hand USP 3/0 (2 metric) polyglyconate (Maxon®, Davis and Geck) or polydioxanone (PDS®, Ethicon Ltd, Edinburgh, UK) are suitable for this purpose.

A BAR of appropriate external diameter and gap-width is selected, using EEA® (US Surgical Corporation and Auto Suture UK, Ascot, UK) 'sizers' if desired. The BAR is inserted into the proximal bowel end first by means of the plastic handle provided (*Figure 3a*) The purse-string is tied snugly, but not too tightly as this may cause necrosis and early passage of the intact device. The plastic handle is removed and the BAR is inserted into the distal bowel (*Figure 3b*). Correct alignment of the mesentery is confirmed and the second purse-string is tied The device is closed by index finger and thumb pressure of two hands, 180° apart, and usually results in an audible or palpable click Additional serosal supporting sutures were inserted by some surgeons if complete serosal apposition was uncertain

Two hundred and two patients undergoing elective colorectal procedures were prospectively randomized to undergo anastomosis using either conventional techniques (sutures or staples) or the BAR Randomization was stratified to compare the device with both sutures and staples, and the surgeon elected at operation after resection which 'control' method would be his usual choice. Only then was a randomization envelope opened to select the anastomotic technique. The number of stapled patients was small, and no significant differences emerged between the sutured and stapled groups. All comparisons between groups were made using the χ^2 test with Yates' correction for continuity Informed consent was obtained from all patients taking part, and the trial protocol was approved by the local ethical committee in all the participating hospitals

Anastomotic leakage, wound infection and subacute obstruction rates reported are those detected clinically. No routine radiological contrast studies were performed in this series.

Results

There were no significant differences between the groups of patients, which were well matched for age, sex, incidence of malignancy and inflammatory bowel disease (*Table 1*). Anastomoses constructed are shown in *Table 2*, and the BAR sizes used are shown in *Table 3*. Techniques of bowel preparation and perioperative antibiotic usage are shown in *Table 4*. Adequacy of bowel preparation was reported as excellent or good in 84 per cent of cases, and as poor in only 3 per cent, with no differences between groups.

No intraoperative complications of sutured anastomoses were reported. One stapled anastomosis was unsatisfactory; this was taken down and a sutured anastomosis performed.

Twelve anastomoses using the BAR were technically difficult to complete. One rectum was split with an EEA sizer, and four purse-strings failed using the modified purse-string instrument. The remaining seven problems (6·9 per cent) were specific to

the BAR: in three cases the device was too large to enter the small intestine or colon, or a serosal tear occurred; in two cases thick bowel wall was difficult to place within the 6-mm open gap (*Figure 2*); and in two cases it was difficult to place the device into the second (distal) bowel lumen in the pelvis. A second BAR was successfully inserted after failure of a purse-string but, in four cases of difficulty, BAR anastomosis was abandoned in favour of a sutured (three cases) or stapled (one case) anastomosis. In three of the cases the BAR was too large or tearing occurred, and in the fourth the bowel wall was too thick to permit safe insertion of the device.

There was no significant difference in the postoperative return of bowel function, or the length of hospital stay, in the BAR or control groups.

Twenty-two patients were aware of passing remnants of the BAR. Two complained of some anal discomfort after passage,

BAR, biofragmentable anastomosis ring

and one BAR became impacted in the anal canal. This had to be broken up to facilitate passage.

Principal postoperative complications are shown in *Table 5*. All five deaths were due to cardiac or respiratory complications, and unrelated to the surgical technique. There was no statistically significant difference in the anastomotic leakage rate from BAR anastomoses (two cases) and control anastomoses (eight cases) but the leakage rate was skewed by an additional surgeon at one hospital whose sutured patients had four anastomotic leaks, while his BAR patients had one leak. This one surgeon was associated with 50 per cent of the anastomotic failures in the study, and his anastomotic leak rate for sutured anastomoses was significantly greater than that of all the other surgeons involved ($\chi^2 = 17{\cdot}6$, d.f. $= 1$, $P < 0{\cdot}001$).

Postoperative subacute small bowel obstruction occurred in six patients: three after anastomosis with the BAR, one after sutured anastomosis and one after stapled anastomosis settled with conservative treatment. One patient in the BAR group required laparotomy on the tenth postoperative day for division of adhesions between the small intestine and the abdominal wound. All episodes of subacute obstruction involved the small bowel, and in no case was there evidence of mechanical obstruction at the level of the anastomosis, whether this was performed using the BAR, sutures or staples.

Discussion

Animal studies in dogs and pigs[5,6] have shown the BAR to be as effective as sutures or staples for construction of a colonic anastomosis. Intraluminal pressures required to disrupt the anastomosis in pigs was greater for the BAR than for sutures or staples[5]. Anastomoses with the BAR had greater vascular congestion than those which were sutured or stapled, with an increased inflammatory response. However, the incidence of necrotic muscle wall at the anastomosis was lowest in the BAR animals at 16 days, and fewer foreign body giant cells and microabscesses were seen than with the other techniques[5]. Decreased residual granulation tissue present at 1 year suggests that the BAR may even be biologically superior to other anastomotic methods.

Early clinical experience from one centre[7] was encouraging, and the present study was set up to evaluate the device by a number of different surgeons in different hospitals. In most cases the device was quick and easy to use. The purse-string sutures can be placed accurately using either the modified Furness clamp or by hand, but unsatisfactory purse-strings must be replaced, as inaccurate placement of the bowel ends within the device may lead to failure of its closure or to an anastomotic leak.

Serosal tearing, by injudicious use of unduly large sizers or use of too large a BAR, also appears to be hazardous as the device works by maintaining serosal apposition. A serosal defect combined with ischaemia of the remaining bowel wall[8] due to pressure from too large a device may have contributed to the two BAR leaks. These hazards may be avoided by careful assessment of luminal size, choice of the appropriately sized BAR, and use of a side-to-end technique particularly for narrow terminal ileum.

The open gap-width of 6 mm made use of the BAR difficult in two patients with very thick bowel wall, and this may at present be a relative contraindication to its use. The device was used in the upper rectum and its use in the middle third is being investigated. There is no transanal insertion technique at present, thus precluding its use for low anterior resection. Development of a transanal introducer, or separation of the device into two parts for individual placement in the bowel ends and subsequent locking, would extend the usefulness of the BAR. There was no difference in the anastomotic leak rate or wound infection rate between the groups. The apparently lower anastomotic failure rate for the BAR may be confirmed statistically by study of larger numbers of patients. One surgeon had a significantly increased anastomotic failure rate; excluding the 14 patients upon whom he operated the anastomotic leak rate for the study (BAR 1, staple 1, suture 3; 5/188 = 2·7 per cent) was acceptable for elective colorectal surgery.

This device produces a safe, rapidly executed anastomosis. The lack of granulation tissue and scarring at 1-year evaluation in animals may indicate its superiority over the stapled anastomosis with its tendency to stricture. Many European surgeons do not usually use staples for intraperitoneal large bowel anastomoses, but the BAR is theoretically attractive for the patient with inflammatory bowel disease, diverticulitis, or impaired healing for other reasons, and further clinical evaluation in these groups is necessary. Animal work has already confirmed the safety of the device in animals given steroids[6], and after irradiation of the bowel[9]. Speed of use for multiple anastomoses is attractive in major intra-abdominal trauma, and in the severely debilitated patient. Further assessment in these groups is awaited.

In 1902, Jeannel commented on Ramaugé's version of Murphy's button: 'I believe I know how to sew, yet I side with the boutonnistes. Is it to be denied that for the average surgeon it is easier to apply an anastomotic button than to suture an anastomosis? And moreover, when the suturists point to the failures of the button, have they forgotten their own failures? Who dares pretend that sutures have not claimed, and will not continue to claim, more victims than the buttons.'[10].

The Valtrac BAR represents a button fulfilling Senn's criteria introduced to current surgical practice, and preliminary assessment is encouraging. Our evaluation of the BAR in

patients undergoing elective colorectal surgery has confirmed its safety and efficacy compared with established techniques. Further evaluation in high risk groups may confirm its superiority, and evaluation in other gastrointestinal anastomoses may extend the indications for clinical use of the BAR.

A more realistic way of practising surgical knots using a surgical glove

A. S. E. Younger and A. A. Gunn

Department of General Surgery, Bangour General Hospital, Broxburn, West Lothian EH52 6LR, UK
Correspondence to: Mr A. A. Gunn

Practising surgical knots outside the operating theatre is an essential part of training. The techniques can be learned from any manual[1], although hours of practice on coffee cup handles and the backs of chairs can still lead to inexpert fumbling in theatre as tissue has a different resistance to pull on suture material.

A blown-up surgical glove with the wrist tied is an excellent simulator of tissue with five fingers on which to tie. As the glove fingers have little resistance to pull, traction across the knot using the index fingers to 'bed' the knot down must be used to prevent the knot being pulled clear. After each knot has been tied, its security and tension can be checked by cutting off the 'finger' distal to the ligature and seeing if the glove deflates.

Further problems arise when the trainee returning to theatre has to tie round held artery forceps. However this can be practised using forceps as in *Figure 1*.

By learning the technique trainees will avoid pulling their sutures off vessels, thus gaining their own confidence and that of their supervisors.

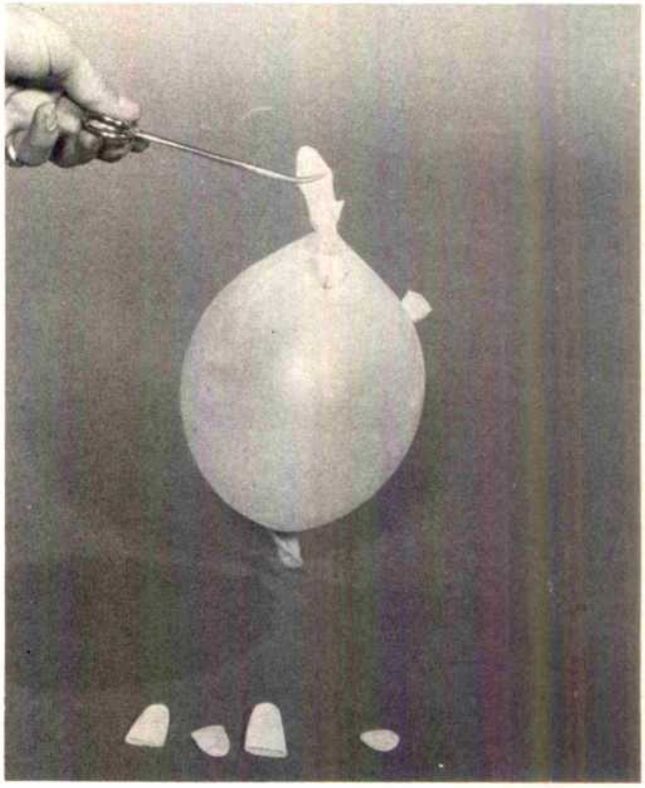

Figure 1 *Four secure knots on four glove fingers. The use of artery forceps is shown*

Stapling technique for pouch–anal anastomosis without the need for purse-string sutures

N. S. Williams

Surgical Unit, The London Hospital, Whitechapel, London E1 1BB, UK

Correspondence to:
Professor N. S. Williams

Pelvic pouch–anal anastomosis for the surgical treatment of ulcerative colitis is now an established technique[1,2]. The anastomosis is invariably performed trans-anally after sleeving the pouch through a short, denuded rectal stump. In an attempt to simplify the operation and to improve function, some authors have performed an end-to-end stapling anastomosis between the ileal pouch and the anal canal, eliminating the need for mucosectomy[3,4]. Similarly, colonic pouches have also been constructed and anastomosed trans-anally to improve function after low anterior resection[5,6]. The latter anastomoses have all been performed manually. We report a technique using a circular stapling instrument, which can be used either for colonic pouch–anal or for ileal pouch–anal anastomosis. The technique eliminates the need for distal and proximal purse-string sutures and thus reduces the associated risks.

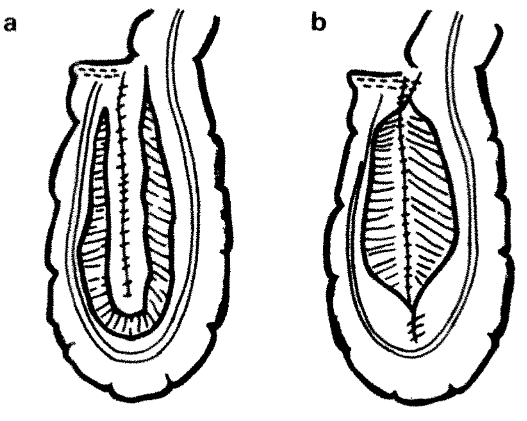

Figure 1 **a** *A J colonic pouch is constructed from the descending colon;* **b** *a defect is left in the anterior wall*

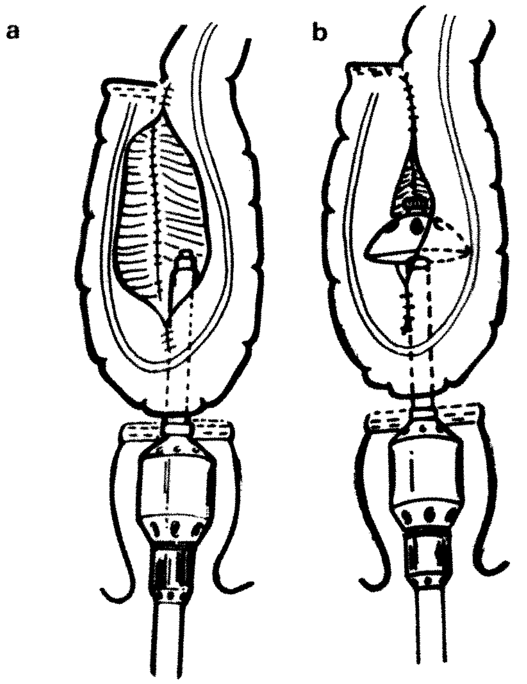

Figure 2 **a** *The shaft of the stapling gun without the head is inserted first through the stapled rectal stump and then through the apex of the pouch, so that it appears through the anterior wall defect of the pouch.* **b** *The head of the gun is screwed onto the shaft*

Technique

The description will concentrate on the colonic pouch procedure since end-to-end stapled colonic pouch–anal anastomosis has not been reported previously. The left colon and distal half of the transverse colon are mobilized in the usual way for a low anterior resection. The rectum containing the carcinoma is mobilized down to the pelvic floor. The dissection encompasses all the mesorectum, as described by Heald *et al.*[7], and allows a minimum distal margin of clearance of 2 cm (Reference 8). Division of the anococcygeal attachments allows the rectum to be lifted forwards between the two levator muscles. The rectum is strongly retracted upwards and a right-angled clamp is applied just above the proposed level of transection. The rectal stump is then irrigated with a cancericidal agent (1 per cent cetrimide solution). An appropriate transverse stapling instrument is applied to the taut rectum below the right-angled clamp at the level of the levators, and is fired. The transverse stapler can be applied at an even lower level if an assistant exerts strong upward pressure by a fist inserted between the ischial tuberosities. If any difficulty is experienced in applying the stapler, the right-angled clamp can be removed and then re-applied after the stapler has been fired. The rectum and left colon are then excised as for a conventional anterior resection. A J colonic pouch is partially constructed (6-cm limbs) manually after first ensuring that it will reach the pelvis. The central part of the anterior wall of the pouch, however, is not completed, thus leaving a defect (*Figure 1a* and *b*).

The shaft of the disposable circular stapling gun (size 28 or 30 mm) without the head is inserted through the anorectal stump by an assistant, so that it emerges through the anterior or posterior wall as far away from the transverse stapled line as possible, although this is not crucial. The gun is racked open to its fullest extent. A stay suture is placed on the apex of the pouch at the limit of the anterior suture line. A long artery forceps is inserted through the defect in the anterior wall of the pouch and gently pushed through the apex of the pouch, well away from the suture lines. Using the artery forceps as a guide, the shaft of the gun is passed into the lumen of the pouch to emerge through the anterior wall defect (*Figure 2a*). The head of the instrument is then screwed securely to the shaft (*Figure 2b*). The anterior wall of the pouch is completed with the head of the gun within the pouch lumen (*Figure 3*). The head and the shoulder-piece of the gun are then racked together in the usual manner (*Figure 3*). Gentle pressure applied by the assistant upwards on the gun enables the anorectal stump to be seen clearly. Similarly, gentle traction upwards on the colonic pouch by the abdominal surgeon allows both the pouch and the anorectal stump to be approximated without extraneous tissue interposing between them, and traction anteriorly on the stay suture ensures that the anastomosis is constructed well away from the suture lines of the pouch. The gun is fired when apposition is complete, and removed in the usual way. The integrity of the 'doughnuts' is then checked. The procedure can be modified for an ileal pouch, whether it be of the J , triplicated or W configuration.

Although the technique described uses the conventional circular stapling instrument, the operation can be performed with little modification using the new Premium EEA® (US Surgical Corporation and Auto Suture UK, Ascot, UK) instrument. If the latter is used, the shoulder-piece of the instrument with its central, pointed pin *in situ* is inserted into the anorectal stump so that the pin penetrates the wall. After the instrument has been fully racked open, the central pin is removed. The separate anvil pin, together with its attached head, is inserted into the pouch through the anterior wall defect, and the pin is gently pushed through the apex of the pouch away from the suture lines of the pouch. The anvil pin is then inserted into the hollow end of the main shaft of the instrument as it emerges from the anorectal stump. It is important to ensure that the anvil pin is pushed home and clicked into position. The head and shoulder-piece are then racked together in the usual way, and the gun is fired.

Discussion

Recent data on pathology[9] have shown that microscopic radial spread of rectal cancer is common and that surgeons frequently leave these deposits behind, even when they believe at the time of operation that they have performed a curative resection. To ensure the removal of as much microscopic disease as possible, it seems logical to excise all the mesorectum, irrespective of the height of the tumour from the anal verge[7]. Unfortunately, such a manoeuvre may leave behind an ischaemic rectal stump. To prevent this problem, it is perhaps safer to remove the entire rectum and to leave just the anal canal. Although anastomosis of colon to a short anal cuff results in continence, patients often suffer severe frequency of bowel action[10]. The cause seems to be a combination of low resting anal pressure and reduced 'rectal capacity'[11]. To overcome the problem, Lazorthes *et al.*[5] and Parc *et al.*[6] suggested the use of a J colonic pouch, which they anastomosed via the peranal route[12] to the anal canal. Their technique overcame the problem of reduced rectal capacity, and function has been shown to be superior to a straight coloanal anastomosis[13]. Nevertheless, since their technique requires that the anal sphincter be stretched for some time during construction of the anastomosis, it is likely that damage will still be inflicted on the sphincteric mechanism. To eliminate this problem, it was decided to construct the pouch-anal anastomosis by end-to-end anastomosis using the stapling gun. Such an approach has been found to produce better functional results when ileal pouches have been anastomosed directly to the anal canal in patients with ulcerative colitis[4]. To simplify the technique even further, and to ensure a secure stapled anastomosis, the original technique has been modified by eliminating the need for purse-string sutures.

The construction of a secure stapled anastomosis relies on the accuracy of placement of the purse-string sutures to each end of the bowel lumen to be anastomosed. The suture may not run smoothly through the tissues when the knot is tied, and consequently the tissue is not applied satisfactorily to the shaft of the instrument. Even if the purse-string suture does run smoothly, tissue may be so bunched up in the gap between the shoulder-piece and the head that a complete circumferential anastomosis is not possible. The purse-string may cut out when tied, or may snap, necessitating re-insertion. To avoid some of these problems, several authors[14–16] have eliminated the distal purse-string by transverse stapling of the distal anorectal stump. However, through necessity the proximal purse-string was retained. The formation of a pouch, whether colonic or ileal, provides the opportunity also to eliminate the proximal suture and to make the anastomosis even more secure.

The technique described can be performed using either the conventional circular stapling instrument or the new Premium EEA. The latter instrument has been used on several occasions and, although it is simple to use, it only marginally streamlines this particular technique. A possible future complication is the greater propensity to anastomotic dehiscence owing to the possibility of devascularization of the pouch apex. To date, the first 20 patients treated in this way have had no more anastomotic complications than those patients with a conventional anastomosis. Clearly, however, carefully controlled data will be required before this question can be answered fully.

An improved technique of J pouch construction and ileoanal anastomosis

W. A. Brough and P. F. Schofield

Department of Surgical Gastroenterology, Withington Hospital, Manchester, UK

Correspondence to: Mr P. Schofield, Teaching Unit 5,
Withington Hospital, West Didsbury, South Manchester
M20 8LR, UK

The technique for the construction of a J shaped ileal reservoir with ileoanal anastomosis after proctocolectomy was first described by Utsunomiya *et al*[1] in 1980. This technique requires four enterotomies to allow entry of a GIA50® (US Surgical Corporation and Auto Suture UK, Ascot, UK) stapling device to create the pouch.

We have modified this and combined it with other surgical techniques to allow a simple and rapid pouch construction and ileoanal anastomosis.

Method

J pouch construction

The 40 cm loop of terminal ileum is fully mobilized. Three chromic catgut stay sutures are placed in the antimesenteric border of the bowel to approximate the two 20-cm limbs of ileum. A Prolene® (Ethicon Ltd., Edinburgh, UK) purse-string suture is inserted at the apex of the J, and an enterotomy is made in the centre of the purse-string (*Figure 1*). The new GIA90® (US Surgical Corporation and Auto Suture UK) stapling instrument is introduced through the enterotomy and the instrument is 'fired' (*Figure 1*). Through a second enterotomy in the proximal part of the afferent limb a second GIA90 stapling device is inserted and fired after ensuring an overlap of the two suture lines to avoid a mucosal bridge from a segment of unstapled pouch. Alternatively, by telescoping the bowel repeated applications of the GIA50 stapler can be made through the same enterotomy at the apex of the J allowing fast, easy and accurate construction of the pouch[2]. The result is a large J pouch with good mucosal apposition and a single enterotomy at the apex of the J. The distal end of the ileum is anastomosed end-to-side with the pouch using two layers of chromic catgut to avoid stenosis of the pouch entrance.

Ileoanal anastomosis

The rectum is fully and carefully mobilized to the pelvic floor by close dissection in all four quadrants. The bowel is divided in the mid-rectal region with no attempt at this stage to remove excess rectum. The anus and remaining rectum are everted[3,4] and traction is applied to demonstrate the dentate line. A Prolene purse-string suture can then be accurately placed 1 cm above the dentate line (*Figure 2*). This allows a 1 cm margin for the resected 'doughnut' after the residual rectum has been excised up to the purse-string. This negates the need for mucosal proctectomy. The purse-string is then passed through the anus to the abdominal surgeon and the anus is inverted.

The detachable anvil of the new Premium curved EEA® (US Surgical Corporation and Auto Suture UK) stapling gun (size 31 mm) is passed through the enterotomy of the J pouch and secured with the previously placed Prolene purse-string suture (*Figure 3*). The Premium curved EEA gun without the anvil is introduced into the anus in the fully extended position. The purse-string in the lower rectum is then tightened around the lower head of the Premium gun. The detachable anvil and J pouch are then passed into the pelvis and the anvil is 'locked' home into the central column of the stapling gun (*Figure 4*). The stapling device is tightened and fired. The result is a large stapled ileoanal anastomosis.

Discussion

The GIA50 stapler for constructing a J shaped pouch is not original[1]. However the modified technique of only one enterotomy[2] in combination with the longer GIA90 stapler allows rapid and accurate construction of the pouch. The single enterotomy is then incorporated into the ileoanal anastomosis. In contrast to Slutzki *et al.*[4], we use a Prolene purse-string suture in the apex of the J pouch to secure the detachable anvil of the Premium curved EEA gun.

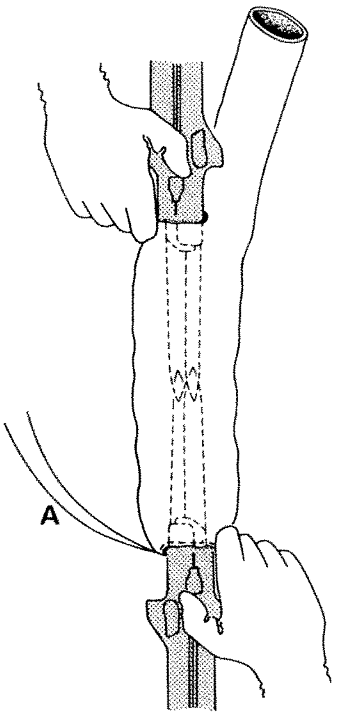

Figure 1 *Formation of J pouch with two GIA90 stapling devices. The Prolene purse-string (A) is placed at the apex of the pouch*

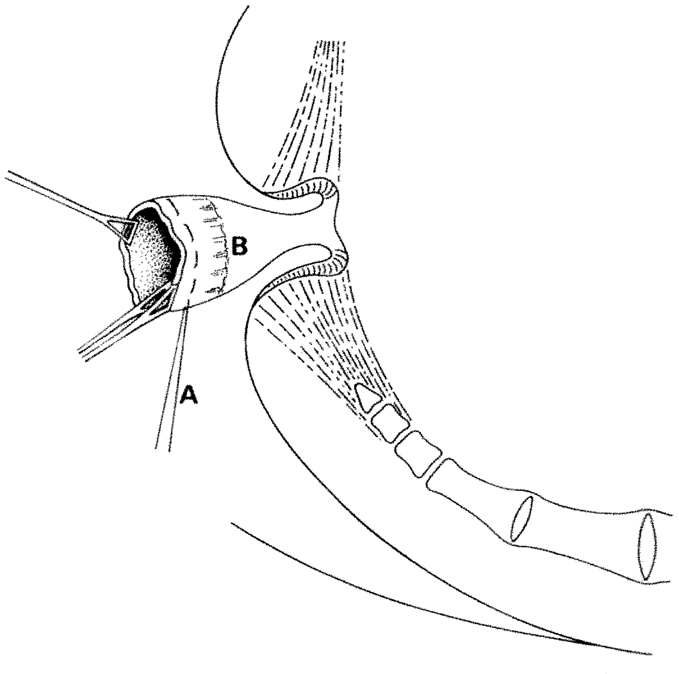

Figure 2 *Everted rectum and anus. The Prolene purse-string (A) in situ 1 cm above the dentate line (B)*

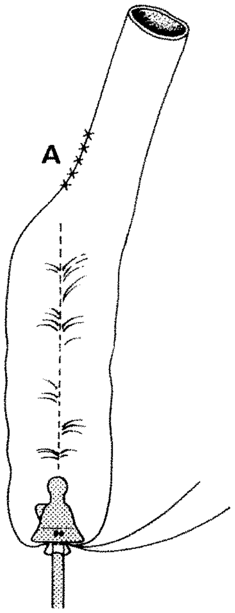

Figure 3 *Insertion of the detachable anvil into apex of J pouch. The distal limb (A) has been anastomosed to the afferent limb*

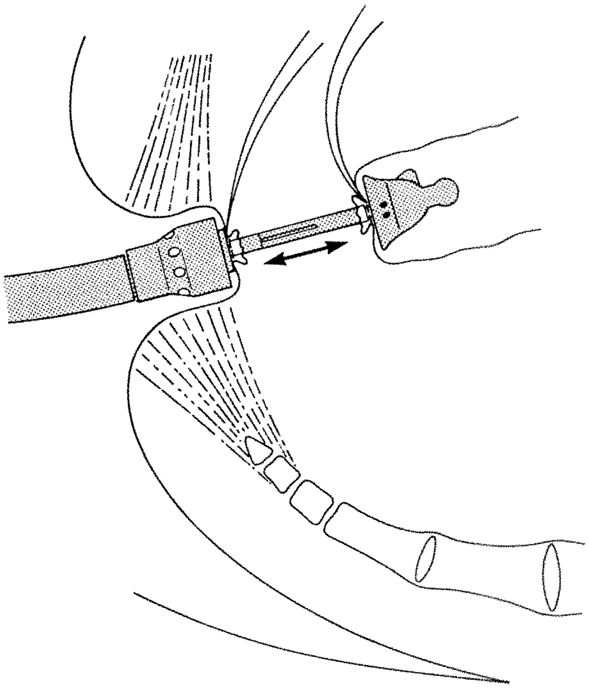

Figure 4 *The Premium curved CEEA gun in position with the J pouch containing the detachable anvil brought into the pelvis*

Eversion of the anus is not a new technique and does not alter anal function[3,4]. In this operation eversion of the anus facilitates the placing of the lower purse-string which allows the remaining mucosa to be removed as a 'doughnut' of rectum. In contrast to the technique for performing low anterior resection of the rectum we find it easier to invert the anus after placing the purse-string because the lower head of the gun does not completely enter the anus when in the correct position for firing. Tying of the lower purse-string is made easier as the detachable anvil is not in position. After securing a good distal purse-string the anvil and J pouch are approximated. This modified technique allows: (1) rapid construction of a J pouch, (2) accurate and easy placing of both purse-string sutures, and (3) removes the need for mucosal proctectomy.

We have used this technique in the formation of ten ileoanal anastomoses. Water soluble contrast studies at 7 days outlined a large pouch with no leaks. This may suggest that a covering ileostomy is not necessary. Satisfactory 'porridge tests' (ability to retain 180 ml semisolid porridge) confirmed continence in all cases before closure of the ileostomy. Early results show that patients are continent at night with a median stool frequency per 24 h of 5 (range 3–9). Anal manometry is within the normal range. This method of proctocolectomy and ileoanal pouch construction is rapid, safe and shows promising early results.

Fifty patients attending for surgical treatment of chronic constipation (n = *21*) *or faecal incontinence* (n = *29*) *were studied using two psychiatric screening tests: the Hospital Anxiety and Depression (HAD) scale and the General Health Questionnaire (GHQ). Each patient was assessed preoperatively and 6–12 months postoperatively. Results were compared with age and sex-matched controls* (n = *50*)*. Constipated patients had significantly higher HAD depression scores compared with controls (median and range): 6 (2–12)* versus *4 (0–8),* $P < 0.05$*. Constipated patients who were improved by operation* (n = *13*) *had significantly lower preoperative HAD anxiety scores compared with those who were not improved* (n = *8*)*: 8 (3–14)* versus *15 (10–19),* $P < 0.01$*; they also had significantly lower HAD depression scores: 4 (2–12)* versus *7 (5–11),* $P < 0.05$*. Using these parameters incontinent patients did not differ from controls, but patients who had a bad result after operation* (n = *15*) *had significantly higher HAD anxiety scores than those who obtained clinical benefit* (n = *14*)*: 10 (2–15)* versus *6 (2–12),* $P < 0.05$*; HAD depression scores were also greater: 5 (2–15)* versus *3 (0–9),* $P < 0.05$*; and GHQ scores were greater: 12 (0–47)* versus *4 (0–41),* $P < 0.05$*.*

Keywords: Incontinence, constipation, psychiatric screening

Some patients with constipation or incontinence have a history of anxiety or depression. Although a functional component is recognized in the irritable bowel syndrome[1,2], patients with chronic constipation or faecal incontinence have not been subject to such rigorous psychiatric assessment. Most coloproctologists are aware that patients with chronic constipation are emotionally labile and may exaggerate their symptoms; some patients may have a personality disorder and a few have underlying psychiatric disease. These features appear to be less common in patients with faecal incontinence, and emotional factors are often considered to be secondary to the humiliation experienced by their physical disability. We have investigated the value of psychiatric screening tests in predicting the outcome of surgical therapy in these two disorders of defaecation.

Patients and methods

We have carried out a prospective study amongst 21 constipated and 29 incontinent patients. Screening for anxiety or depression was performed using the Hospital Anxiety and Depression (HAD) questionnaire and the General Health Questionnaire (GHQ)[3,4] scales before and after surgical treatment by one person. Results in patients were compared with age and sex-matched controls. Controls consisted of patients with other unrelated disorders: gallstones, varicose veins and impacted wisdom teeth. Controls completed their questionnaires under the same conditions as the patients. Results were not analysed until completion of the study since we did not wish to modify our surgical decisions on the results of the questionnaires. The surgical procedures offered to patients were based upon clinical and physiological assessment of anorectal function using anal and rectosigmoid manometry, electromyography, passage of transit markers and videoproctography[5-8].

All patients entering the study had been referred for surgical treatment. Underlying medical conditions or drug therapy leading to constipation or incontinence had been excluded, and conservative therapy had been unsuccessful in all patients. No patient was receiving psychiatric therapy when entered into the study.

From 6 to 12 months after operation repeat assessment was performed using the HAD and GHQ scales. The outcome of operation was based on assessment by an independent observer who was unaware of the results of the HAD and GHQ scores.

The HAD scale consists of seven questions relating to symptoms of anxiety and a further seven relating to symptoms of depression. Four alternative responses are available for each question and a score of between 0 and 3 is awarded depending on the option chosen by the patient. By adding the scores a numerical rating for anxiety and depression is obtained.

The GHQ consists of 60 questions with four options per question. These are arranged to show increasingly abnormal symptoms from left to right. The two left-hand columns score 1 and both right-hand columns score 2. The scores are added to give an overall psychiatric rating. No attempt was made during this study to assess the reproducibility of the tests used.

Results were compared using the Mann–Whitney *U* (two-tailed) test.

Results

Of the 50 patients recruited to the study, follow-up questionnaires 6–12 months after operation were completed by 46; three failed to keep their follow-up appointment and one patient had been admitted to a psychiatric hospital because of severe depression.

Comparison between preoperative scores for each group and controls are shown in *Table 1*.

Constipated patients had significantly higher HAD depression scores than controls (*Figure 1*) ($P < 0.05$). Constipated patients who had a good result following operation did not differ from controls (*Figure 2*), whereas those who had a poor outcome differed significantly from controls for all three parameters (*Figure 3*). A comparison was made between those patients who benefited from surgery and those who did not; those with a poor functional result had significantly higher anxiety ($P < 0.01$) and depression ($P < 0.05$) HAD scores than those who did well (*Figure 4*).

When the same analyses were applied to the incontinent patients, no significant differences were demonstrated between

the patients and controls (*Figure 5*). Comparison between those who did well and those who did not showed that clinical benefit was associated with significantly lower HAD anxiety scores ($P<0\cdot05$), lower HAD depression scores ($P<0\cdot05$) and significantly lower GHQ scores ($P<0\cdot05$) (*Figure 6*).

Comparison between preoperative and postoperative scores indicated that none of the groups changed significantly during follow-up. There was no correlation between any of the scores and the physiological data obtained during assessment of anorectal function.

Discussion

The role of psychological and emotional factors in the aetiology of organic disease remains unclear. In the field of gastroenterology most attention has been focused on the irritable bowel syndrome. In a recent review, Creed and Guthrie[9] discussed psychological factors in irritable bowel syndrome. When a psychiatric disorder is diagnosed in a patient with organic symptoms it is possible that the patient may have developed both simultaneously, that the psychiatric disorder may precipitate fixation on organic symptoms, or that the presence of chronic organic symptoms may have an effect on the patient's behaviour.

In this study all patients had evidence of clinically important abnormalities of anorectal function. Our study was designed to determine whether there was any evidence of emotional disturbance amongst patients with incontinence or chronic

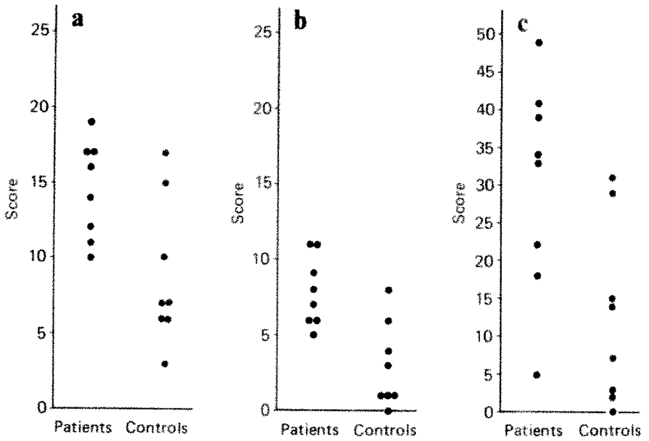

Figure 3 *Preoperative scores in constipated patients who were not improved by surgery.* **a** *Hospital Anxiety and Depression (HAD) scale, anxiety scores,* **b** *HAD scale, depression scores,* **c** *General Health Questionnaire scores*

constipation compared with controls who had a normal bowel habit. In particular we wished to ascertain whether the operation had any effect on these parameters of anxiety and depression and to identify whether patients who did badly after the operation could be identified preoperatively.

Both screening tests have been developed as self-assessment scales to detect emotional and psychiatric traits. The HAD scale has been designed specifically for use in hospital patients as a means of identifying states of anxiety and depression. The questions are structured so that symptoms which may be of organic or psychiatric origin are excluded; hence the questionnaire is valid for use in patients with physical symptoms. These scales can be used both to study populations and to identify individuals who might benefit from a more comprehensive psychiatric assessment.

The GHQ identifies non-psychotic abnormalities without attempting to provide a specific diagnosis. The 60 questions are grouped. Some are largely somatic symptoms and others are psychiatric. This can lead to difficulties in interpreting high scores in patients with organic illness. The GHQ is a useful assessment of population differences and may also be used to screen individuals. The scale assesses severity of symptoms, but Goldberg[4] reported improved sensitivity and specificity when both minor responses were graded 0 rather than using sequential scores from 1 to 4.

This study suggests that incontinent patients have a similar emotional profile to age and sex-matched controls. Patients who did badly after postanal repair for faecal incontinence had significantly higher preoperative scores for all three parameters than those in whom continence was restored. This finding might be explained if patients with high score have the irritable bowel syndrome since it is known that if episodes of unheralded diarrhoea persist after operation clinical results are poor[10]. Alternatively, persistently high scores may reflect a group of patients who feel socially isolated because of persistent faecal incontinence, particularly as many realize that they may need a permanent stoma. There was no deterioration in the scores of anxiety and depression after operation in patients who had a poor clinical outcome. Hence it is unlikely that preoperative expectations and subsequent disappointment in the outcome is relevant. Since the status of these patients is independent of the operation, it is concluded that preoperative differences may predict the outcome of surgical treatment in incontinent patients.

Constipated patients had significantly higher depression scores preoperatively than controls. It also became clear that constipated patients who fared badly after surgery had abnormal preoperative scores for each parameter tested when compared with controls and with the patients who did well. A review of the scores for individual patients indicates that all eight patients having a poor surgical result had sufficiently high HAD scores to recommend a more thorough psychiatric assessment. This compares with only four of 13 with a good result and six of 21 controls. Probably because of its greater somatic content, the GHQ was less selective than the HAD

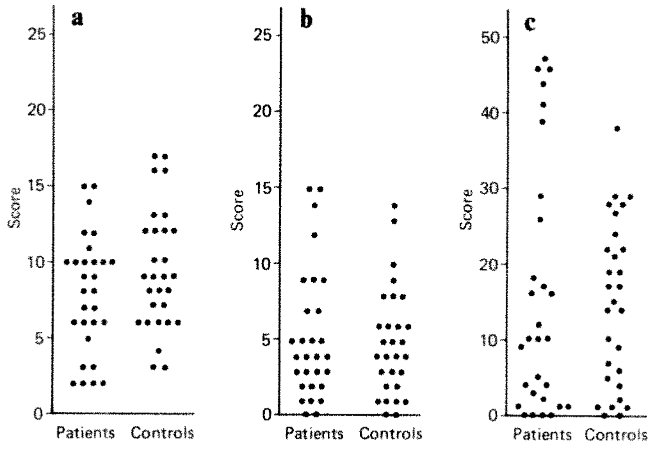

Figure 5 *Scores for all incontinent patients.* **a** *Hospital Anxiety and Depression (HAD) scale, anxiety scores,* **b** *HAD scale, depression scores,* **c** *General Health Questionnaire scores*

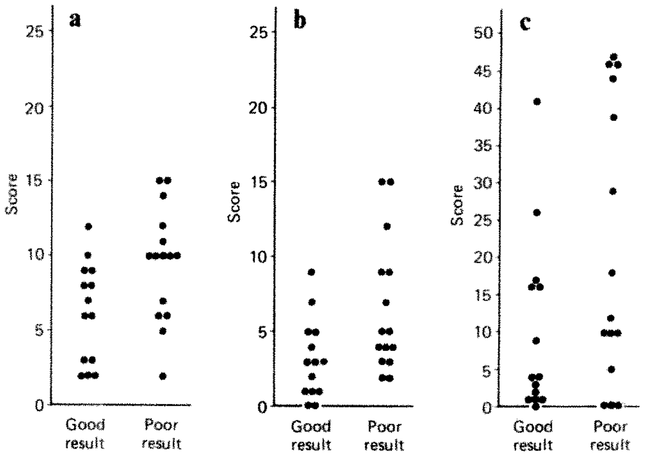

Figure 6 *Scores for incontinent patients with good results and with poor results.* **a** *Hospital Anxiety and Depression (HAD) scale, anxiety scores,* **b** *HAD scale, depression scores,* **c** *General Health Questionnaire scores*

scale. The GHQ identified seven out of eight of the group who had a poor surgical result but also six of 13 patients who did well and 11 of 21 controls who might have merited further psychiatric assessment.

It may be argued that the abnormalities detected in this short-term study were the result of acute stress associated with hospital admission and surgical treatment. If this were so, all groups would be expected to have similar scores, and scores would be expected to change to a lower level after successful surgery. This was not the case. No group showed a significant change between preoperative and follow-up scores. It seems more probable that the psychiatric symptoms identified by screening are not caused by the patient's gastrointestinal disorder. An attempt was made to correlate the severity of symptoms and the degree of physiological abnormality with psychiatric score, but no correlation was found. This again suggests that the presence of psychiatric disturbance is associated with a group of patients who fared badly after surgery.

There is a well-defined group of constipated and incontinent patients who do not respond to conventional surgical treatment and who may be identified preoperatively by psychiatric screening. Thorough assessment is advised in patients with high HAD scores who are constipated since there is a recognized correlation between psychiatric disorders and either outlet obstruction or colonic inertia[11,12].

A 2-day meeting was held in Bristol on 5 and 6 July 1988 immediately before the Tripartite meeting of the Surgical Research Society in order to discuss methods and identify areas of agreement with regard to measurement of indices of anorectal physiology. The following report highlights our findings.

Keywords: Anorectal physiology, manometry, sensation, electromyography, videoproctography

Anal manometry

Methods must be stated clearly when reporting the results of anal manometry. If perfused catheters are used the internal diameter of the tubing, its consistency and the size and site of side openings must be recorded. The radial orientation of side holes must be described. The description of the method should indicate whether the technique is one of station pull-through or whether recordings were made by continuous withdrawal, in which case the speed of withdrawal must be recorded. Methods must indicate the rate of infusion, the hydraulic delivery system and the length of the catheter. The commonest method for recording anal pressures is to use a closed water-filled balloon probe. Microtransducers have been used but they fail to correct for radial change and they are expensive.

We could find no consensus on a uniform recording system for anal manometry as the methods used will be influenced by the parameters that need to be assessed. However, damping and inaccuracies over the higher pressure range are recognized with water-perfused catheters. Air-filled balloons are probably the most reliable method for routine manometry. It is recognized, however, that there is a reluctance to change the system of recording if long-term longitudinal studies are needed. For this reason it is accepted that a closed water-filled balloon probe fulfils the requirements for most anal manometry.

It was agreed that anal pressures should be recorded in kilo Pascals (100 cm of water = 9·8 kPa).

It was agreed that maximum resting anal pressure (MRP) should be used to denote the highest recorded pressure at any site in the anal canal at rest.

It was agreed that maximum squeeze pressure (MSP) should be used to denote the highest recorded pressure at any site in the anal canal during maximum pelvic floor contraction.

Rectal sensation

Rectal sensation can be tested by infusion or by incremental volumes of air introduced into a male condom or party balloon mounted on a catheter inserted in the rectum. The sensory response depends on the method used and the position of the patient; both should be stated.

Rectal compliance

It was agreed that the proctometrogram was the best method of measuring compliance. A balloon probe or a microtransducer is inserted inside a male condom and placed in the rectal ampulla. The balloon is continuously perfused with water at 37°C using a constant infusion pump at a rate of 60 ml/min. Compliance is recorded in millilitres per kiloPascal over a volume of between 0 and 1 litre depending on the patient's tolerance. This method was considered to be superior to measurements using insufflation of increments of air into a balloon as results vary with the speed of introducing air and a step-wise change is artefactual.

Electromyography

It was agreed that measurement of fibre density or motor unit potential duration is the only objective assessment of denervation. These measurements should be combined with a method which assesses conduction defects. Measurement of pudendal nerve terminal motor latency seems to be the most widely recognized and reproducible technique for detecting conduction defects in the terminal portion of the pudendal nerve. The pudendoanal reflex is subject to synaptic delay and is not recommended for use. The anocutaneous reflex is associated with three responses, the early responses being due to short-circuiting, hence the reflex is no longer used for detecting conduction defects in the pudendal nerve.

Electromyography is useful for mapping a deficient or ectopic sphincter. The technique is also useful for defining 'anismus'.

Fine wire electrodes are ideal for monitoring electrical activity in the puborectalis, external sphincter and even the internal sphincter, during functional studies of pelvic floor activity.

Proctography

It was agreed that proctography should be performed in the seated position on a water-filled apparatus to obtain lateral projections of the pelvis and perineum. It is desirable to mark the symphysis pubis and the perineal skin as well as the anal canal and the vagina with radio-opaque markers. Video monitor linkage is essential so as to analyse activity from frozen frames taken at rest, during maximal pelvic floor contraction and during attempted defaecation. A thick barium suspension should be used by emulsifying contrast material with cellulose and a known weight and volume should be introduced into the rectum.

Videoproctography provides a means of assessing the speed of evacuation and recordings may be combined with internal and external sphincter EMG and puborectalis EMG as well as anal and rectal manometry.

Anorectal angles may be assessed using the centroid of the rectum such that a line drawn from the centroid to the anorectal junction divides the rectum into two equal areas. Conventional measurement of anorectal angle using the posterior border of the rectum is difficult to define because this line may not be straight particularly during pelvic floor contraction. On the other hand, use of the posterior margin of the rectum is the method that has been used most extensively in the literature and the one that is likely to be adopted in the future. Other parameters which can be measured in relation to the

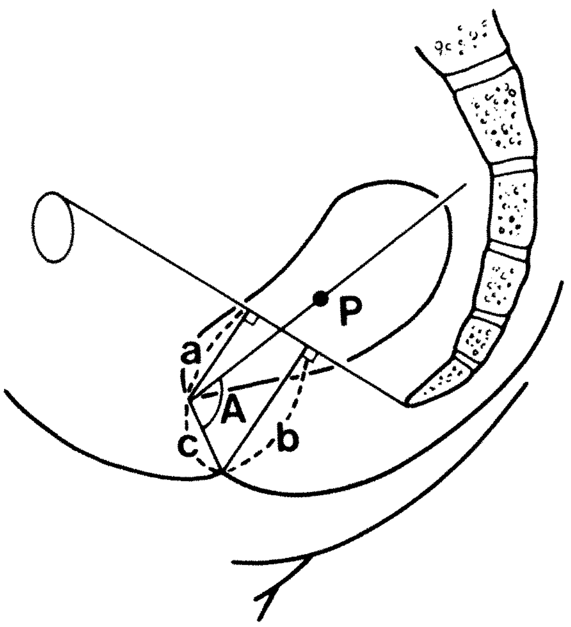

Figure 1 *Anatomical measurement in proctogram. A, anorectal angle; a, pelvic floor descent; b, perineal descent; c, anal canal length; P, centroid. This Figure is reproduced from Yoshioka* et al.[1]

pubococcygeal line and which have predictive function include: pelvic floor descent, perineal descent and anal canal length (*Figure 1*).

There is a need for clear definitions, particularly of abnormalities such as infoldings, rectal and anal intussusception, rectocele, and megarectum as some of these visual abnormalities occur in normal subjects.

The Lahr balloon which was introduced into office practice in North America, is unreliable and should be abandoned.

Isotopic rectal emptying

Isotopic estimation of rectal emptying allows the construction of a time course for evacuation using γ camera images from the pelvis. ^{99}Tc aluminium/magnesium silicate gel provides a useful method of introducing an isotope into a semisolid material having a consistency similar to that of faeces. If this material is introduced into the sigmoid colon an assessment can be made of rectal filling as well as rectal emptying.

Colonic transit studies

It was agreed that the most objective assessment of colonic transit is obtained by asking patients to take three different types of radio-opaque markers each morning for 3 days while they are fully ambulatory and receiving no laxatives. A plain radiograph of the abdomen is obtained on the 4th and 7th day. The abdomen is divided into three areas of interest: the right colon, the left colon, and the rectum and sigmoid area. Mean colonic transit (MCT) can be determined using the formula: $MCT = 1{\cdot}2\ (N_1 + N_2 + N_3)$ where N_1 is the number of the first type of marker, N_2 the number of the second type of marker and N_3 the number of the third type of marker[2].

Colonic motility studies

Colonic motility recordings are difficult to interpret; where possible they should be performed on the unprepared colon using multichannel infusion techniques. The data should be digitized and stored on computer. There will be advantages in the future if studies of colonic motility can be combined with an isotopic assessment of rectosigmoid propulsive activity.

Anal sensation

Assessment of anal sensation is largely a research tool. Mucosal electrosensitivity is the most widely measured parameter and provides an objective assessment of denervation involving the afferent side of the reflex arc of the pudendal nerve[3]. Mucosal electrosensitivity may be measured using bipolar or monopolar electrodes. The technique should be stated.

Rectoanal inhibitory reflex

The rectoanal inhibitory reflex must be assessed at sites throughout the anal canal as it may not be apparent when recordings are made near the anal verge. The reflex is absent after low rectal excision and is normally absent in Hirschsprung's disease. The reflex may also be absent if resting anal canal pressures are low, as in some patients with rectal prolapse for neurogenic faecal incontinence. The response depends on the volume, consistency and speed of rectal filling. The volume required to inhibit recovery of the reduction in resting anal pressure should also be recorded.

It was agreed that a positive response could be defined as any reduction in resting anal pressure after inflation of air into a rectal balloon. The threshold volume needed to elicit the response should be recorded as well as the duration of the reflex.

Localization of lower gastrointestinal bleeding using in vivo technetium-99m-labelled red blood cell scintigraphy

M. L. Nicholson, J. P. Neoptolemos*, J. F. Sharp, E. M. Watkin†, and D. P. Fossard

Department of Surgery, Leicester Royal Infirmary, and †Department of Radiology, Leicester General Hospital, Leicester, UK

Technetium-99m-labelled red blood cell scintigraphy was used in the investigation of 41 patients with major rectal haemorrhage. Red cells were labelled in vivo *with technetium-99m pertechnetate and serial scans (0–36 h) were taken using a large field γ camera. Twenty-two men and 15 women, mean age 71·3 years (range 32–91 years), and four children were studied. Forty-three scans were performed in all and there were 31 positive and 12 negative results. In each case the accuracy of the scan in localizing the bleeding site was checked either by independent investigations or at laparotomy. A definite bleeding site was identified in 30 cases and red cell scintigraphy correctly localized 29 of these (sensitivity 97 per cent). In the remaining 13 cases a bleeding site was not identified by any of the independent investigations and in this group there were two false positive scans (specificity 85 per cent). The investigation had a high predictive value when both positive (94 per cent) and negative (92 per cent). These data suggest that technetium-99m-labelled red cell scintigraphy should be used more widely in the investigation of patients with suspected lower gastrointestinal haemorrhage.*

Keywords: Intestinal haemorrhage, investigation, scintigraphy

The preoperative localization of the bleeding site in patients presenting with lower gastrointestinal haemorrhage remains a difficult clinical problem. Conventional barium studies fail to isolate a potential bleeding site in 20–30 per cent of cases[1] and, even if a lesion is identified, there is no certainty that it is the source of haemorrhage. Colonoscopy can be diagnostic, but profuse haemorrhage usually makes it impractical by obscuring the view. Selective angiography is invasive and only yields a positive result when bleeding is occurring at the time of contrast injection and at a rate $>0{\cdot}5$–$1{\cdot}0\,\mathrm{ml/min}$[2,3].

Radionuclide methods for diagnosing the site of gastrointestinal bleeding have now been available for over 10 years but have not been favoured in this country and were not mentioned in a recent leading article in the *British Medical Journal*[4]. The isotope of choice has invariably been technetium-99m and this has been used to label sulphur colloid[5], albumin[6], diethylene triamine penta-acetic acid (DTPA)[7] and red blood cells[8]. In this paper we report our experience of *in vivo* labelled red blood cell scintigraphy in the investigation of suspected lower gastrointestinal bleeding.

Patients and methods

Patients presenting with major rectal haemorrhage over the 3-year period June 1984–May 1987 were studied. The investigation of the source of haemorrhage in all cases included *in vivo* technetium-99m-labelled red cell scintigraphy. Major rectal haemorrhage was defined as a transfusion requirement of three or more units of blood or an acute fall in haemoglobin level $\geq 20\,\mathrm{g/l}$.

Red cells were labelled *in vivo* by intravenous injection of 1·7 mg stannous chloride and 12 mg sodium pyrophosphate in 2 ml sterile saline, followed 20 min later by technetium-99m pertechnetate in a dose appropriate to the patient's body-weight (range 395–600 MBq)[9]. The stannous pyrophosphate generated binds to red blood cells and then combines with technetium-99m pertechnetate to give labelled red cells. A large field γ camera (Siemens ZLC 370S, Siemens Ltd., Sunbury, UK) with C stand and low energy all purpose parallel collimator was used to perform serial scans, (using 1×10^6 counts per view) starting immediately after isotope injection and continuing at 10-min intervals up to 1 h. If these early images were negative, delayed scans were performed at variable times up to 36 h after isotope injection. Standard anteroposterior views were obtained in all cases, but, where indicated, oblique and lateral views were used to separate possible sites of abnormal activity from background activity in the liver, spleen, kidneys, bladder and great vessels. The investigation was considered to be positive if focal areas of abnormal activity were seen to develop on serial scans (*Figures 1–3*). Negative scans were those which only demonstrated background activity (*Figure 4*).

The sites of bleeding indicated by scintigraphy were compared with the findings of other investigations, including barium studies, colonoscopy and selective mesenteric arteriography, and the findings at laparotomy if performed. In the positive-scan group, the time interval between the injection of isotope and the development of a positive result was recorded for individual scans. The blood transfusion requirements in the 24 h before scanning were recorded and the findings correlated with the scan result. The day after admission on which each scan was performed was also noted.

The accuracy of the isotope scans in localizing bleeding sites was expressed as sensitivity, specificity and predictive values. Statistical analysis was performed using the Mann–Whitney U test for continuous variables and the χ^2 test for discrete variables.

Results

Forty-one patients were studied but as two of these suffered two separate bleeding episodes a total of 43 scans was performed. There were 22 men and 15 women with a mean age of 71·3 years (range 32–91 years) and four children (range 5 months–12 years). The mean haemoglobin concentration at presentation was 9·4 g/dl (range 5·4–13·5 g/dl) and the mean blood volume transfused was 8·2 units (range 3–20 units). Corroborative evidence of the bleeding site was obtained from independent investigations whenever possible. Laparotomy was required in 15 cases and on-table colonoscopy was also used in three of these. The results of routine histological examination of resected bowel were taken into account when deciding the final diagnosis in these cases. In eight patients a

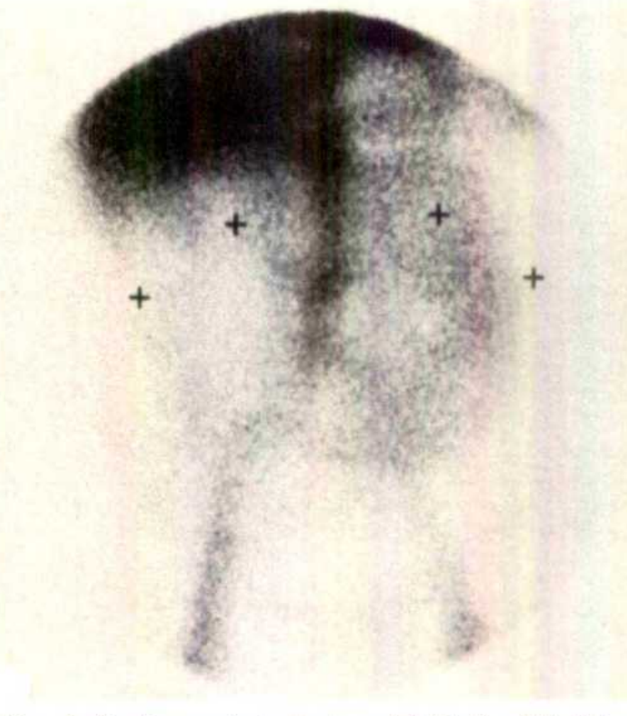

Figure 4 *Baseline scan showing background distribution of labelled red cells for comparison*

lesion was visualized on barium studies, but in each case at least one further investigation was used to confirm that the lesion seen was the source of haemorrhage. In 11 cases the final diagnosis was made at colonoscopy, selective angiography was diagnostic in a further three cases and in one patient the bleeding point was identified at post-mortem examination.

In 30 cases a definite bleeding site was identified. The following diagnoses were made: diverticular disease in 15, angiodysplasia in ten, Meckel's diverticulum in two, small bowel ischaemia in two and recurrent colon cancer at an anastomosis in one case. In the 11 remaining patients no definite bleeding site was established by the investigations used.

Thirty-one scans were positive and in 29 of these the site of haemorrhage demonstrated on scanning was confirmed as correct by independent methods. In the remaining two cases with positive scans, no bleeding point was identified by the other investigations employed and so these scans were taken to be false positive results. Both cases were managed successfully by conservative measures. The remaining 12 scans were negative. However, in one of these patients a bleeding angiodysplastic lesion was seen at colonoscopy and it was successfully treated by diathermy coagulation. This was the only proven false negative result in the series. In the other 11 cases with negative scans no bleeding point was identified by other investigations and the scans were taken to be true negative results. By using the findings of the independent methods of investigation as the standard, *in vivo* technetium-99m-labelled red cell scintigraphy had a sensitivity of 97 per cent and a specificity of 85 per cent. The predictive value of a scan when positive was 94 per cent and when negative was 92 per cent.

Within the group of patients who had a positive and corroborated scan, 15 underwent an operative procedure: right hemicolectomy in five, left hemicolectomy in two, sigmoid colectomy in three, subtotal colectomy in one, laparotomy and biopsy of a recurrent colonic neoplasm in one, small bowel resection in one and Meckel's diverticulectomy in two. Of the other 14 patients with a positive corroborated scan, 13 were managed conservatively and the other, a 5-month-old child with multiple congenital abnormalities, died from massive haemorrhage before surgery.

All of the 11 patients in whom no definite bleeding site could be identified were managed successfully by conservative measures alone. This group was followed for a minimum of 3 months and bleeding did not occur.

The time intervals between the injection of isotope and the development of a positive scan varied considerably (*Figure 5*). Approximately 30 per cent of the 31 positive scans showed a result in the first hour after injection and a further nine became positive between 1 and 6 h. However, a significant number of positive results only developed between 12 and 36 h after injection. As the transfusion rate in the previous 24 h increased, the probability of a scan showing a positive result also increased (*Table 1*).

Figure 6 shows the relationship between the scan result and the time after admission that the scan was performed. Positive scans fell into two distinct groups: those performed in the first 4 days after admission and those performed later during the second week. This latter group represents patients who rebled in hospital. The negative scans did not conform to any particular pattern. In general, positive scans were performed earlier (median 3 days) than negative scans (median 5·5 days), but this difference did not reach statistical significance ($P = 0{\cdot}132$; Mann–Whitney U test).

Table 1 *Transfusion requirements in the previous 24 h and technetium-99m red cell scan results*

Discussion

Localization of the bleeding point remains a difficult clinical problem in the management of patients presenting with major lower gastrointestinal haemorrhage. Two types of lesion which may frustrate even the most thorough investigation are those which bleed slowly and those which bleed intermittently. Successful angiography requires a bleeding rate of 0·5–1·0 ml/min (References 2 and 3) and an important limitation of the technique is that it will only give positive results if active bleeding is occuring at the time of contrast injection. Scintigraphy can detect even lower rates of 0·05–0·1 ml/min[10], but, more importantly, when labelled red cells are used, their long intravascular half-life allows repeated scanning to be performed over 36 h, without injection of further isotope. This greatly increases the probability of isolating a lesion which is bleeding intermittently. Although comparisons between angiography and scintigraphy are inevitable, the two techniques can be complementary and it has been suggested that angiography can be more rationally employed after a positive radionuclide scan has orientated this to the appropriate vessel[2,11].

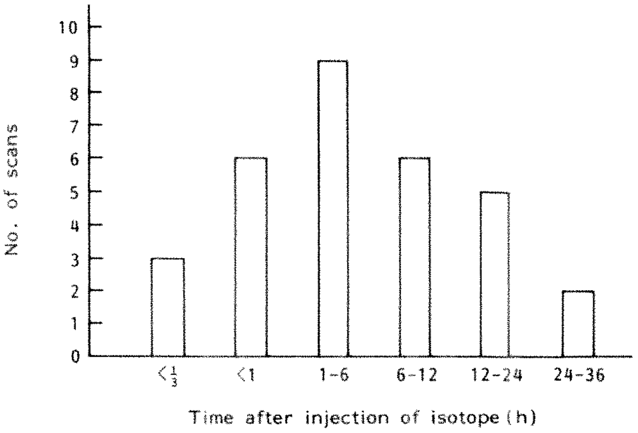

Figure 5 *Positive scans: the time interval from injection of isotope to development of positive result*

Many different isotopic methods have been used for the detection of gastrointestinal haemorrhage. Technetium-99m-sulphur-colloid[5] and technetium-99m-DTPA (diethylene-triamine penta-acetic acid) scanning have the disadvantage, like angiography, that bleeding must be occurring at the time of injection. This is because these radionuclides have a short intravascular half-life, being rapidly cleared by the liver, spleen or kidneys. Furthermore, background counts which appear in the organs that clear these tracers may mask the bleeding point being sought. Technetium-99m-labelled albumin[6] and red cell scans are based on a different principle. These tracers are retained in the circulation, accumulating at a bleeding site and gradually becoming detectable over a period.

Although there are several reports of the successful use of labelled red cell scans in the North American literature[1,8,11–13] the technique has not been reported extensively in the UK. In contrast to our results, false negative rates of 40–50 per cent have been reported[14] and this may be a factor. In our series there were 11 patients with negative scans in whom no bleeding point could be identified by the other investigations performed. By using these independent investigations as the standard against which the accuracy of scintigraphy is calculated, these 11 scans were defined as true negative results. However, it is clear that these patients all had a clinically significant lower gastrointestinal haemorrhage and we accept that the false negative rate may be higher than calculated here. Selective angiography was used very little in our patients but a recent small series did demonstrate technetium-99m red cell scanning to be more sensitive than angiography in localizing bleeding lesions[15]. The procedure is simple and non-invasive and this makes it particularly suitable for critically ill patients.

Red cell scintigraphy can only localize bleeding sites approximately, but we have found that the ability of the method to differentiate between haemorrhage coming from the small rather than the large bowel or from one side of the colon rather than the other was enough to plan surgery logically. This is a major advantage of the investigation because in the past when the cause of colonic bleeding could not be isolated at surgery, the procedure of choice was subtotal colectomy. This operation carries an operative mortality rate of up to 11 per cent[16] and should be avoided if possible.

It is not always clear on purely clinical grounds exactly when a bleeding episode starts and stops and this may cause difficulties in deciding the timing of scanning. However, when three or more units of blood were given in the 24 h before scanning, the ratio of positive to negative scans was very high and so transfusion requirements are a helpful guide. The timing of repeated scans must also be carefully judged because isotope in the gut will move caudally between repeat scans and this could lead to false localization. This problem can be countered to some extent by performing repeated scans at 10–min intervals after any scan which is suspicious of bleeding. In this way bleeding sites can be seen to be developing and the caudal movement on subsequent scans actually becomes a helpful feature in distinguishing a true area of abnormal activity from background activity.

In this study, red cell scintigraphy was successful in identifying bleeding from colonic angiodysplasia. These lesions are so common that they are often seen incidentally at colonoscopy or arteriography, causing considerable confusion when a second lesion is the actual source of bleeding[17].

This study demonstrates that the technique of *in vivo* technetium-99m-labelled red cell scintigraphy is both sensitive and specific in the localization of lower gastrointestinal haemorrhage. Our data suggest that this investigation deserves a more prominent place in the management of lower gastrointestinal bleeding.

Colonic complications of severe acute pancreatitis

Colonic complications are rare in acute pancreatitis. Over the last 9 years at St. Mary's Hospital, London, UK, we have managed severe acute pancreatitis by intensive supportive therapy followed by sub-total pancreatic resection and/or debridement in those who fail to improve. Of the 22 patients who have undergone this form of surgery, nine were found to have colonic involvement in the form of either necrosis or perforation. In addition, one patient presenting at West Middlesex University Hospital, Isleworth, UK, had severe acute pancreatitis and almost total colonic necrosis as an unexpected finding at emergency laparotomy. These ten patients comprised seven men and three women of median age 59 years and with a median of four Ranson criteria. In seven patients, colonic involvement was discovered at the time of pancreatic surgery or laparotomy for pancreatitis and in the remainder it presented between 1 and 3 weeks later as either a faecal fistula (n = *2) or persistent abdominal sepsis* (n = *1). The ascending colon was involved in one patient, the splenic flexure and descending colon in one, the transverse colon in three, the splenic flexure alone in four, and one patient had almost total colonic involvement. All patients underwent resection of the involved colon and exteriorization with either a proximal colostomy* (n = *7) or ileostomy* (n = *3) and a distal mucous fistula. Pathological examination of the resected colons revealed a spectrum of changes from pericolitis through to ischaemic necrosis suggesting at least two possible mechanisms. Six patients died from overwhelming sepsis between 1 day and 4 weeks (median 11 days) after colonic resection. Severe acute pancreatitis must be recognized as a cause of colonic ischaemia and necrosis; this complication is associated with a very poor prognosis despite surgical intervention.*

Colonic involvement is an uncommon but potentially lethal complication of severe acute pancreatitis which has received little attention in the UK surgical literature. It has been estimated that 1 per cent of patients with acute pancreatitis develop a colonic complication[1]. The spectrum of colonic involvement includes: localized ileus which can be seen as the so-called 'colon cut-off' sign[2,3] on a plain abdominal film; mechanical obstruction from either extrinsic compression by a pancreatic inflammatory mass or an intrinsic post-pancreatitic colonic stenosis; fistula formation; and colonic necrosis.

In this paper we report our experiences at St. Mary's Hospital, Isleworth and West Middlesex University Hospital, London, UK, in the mangement of ten patients with severe acute pancreatitis who developed serious colonic complications, namely necrosis and perforation.

Patients and methods

At St. Mary's Hospital during the 9-year period from 1979 to 1987, 22 patients with severe acute pancreatitis have been managed by intensive supportive therapy followed by either sub-total pancreatic resection ($n = 19$) or peripancreatic debridement ($n = 3$). Our experiences in the management of the first 15 of these patients have been reported previously[4]. Of these 22 patients, nine had involvement of the colon to such a degree that the bowel was considered non-viable by the operating surgeon and was resected. In addition, one patient is reported from West Middlesex University Hospital who was found to have severe acute pancreatitis and almost total colonic necrosis at emergency laparotomy for peritonitis. These ten patients form the basis of this report and their clinical features and outcome are summarized in *Table 1*.

Sex and age

There were seven men and three women with ages ranging between 26 and 72 years. The median age of the men in the series was 58 years and that of the women 62 years. The overall median age was 59 years.

Aetiology and severity of pancreatitis

High alcohol intake was thought to be the cause of pancreatitis in six of the ten patients (60 per cent). In addition, two of these patients also had gallstones. Gallstones were the single aetiological factor in two patients. In one man there was no obvious cause for his attack of pancreatitis and one woman developed postoperative pancreatitis following open cardiac surgery and cardiac bypass. All ten patients had severe acute pancreatitis with three or more Ranson criteria[5], the median for the group being four (range from three to seven). Four patients were referred to St. Mary's Hospital from other hospitals because of difficulties in the management of their attack.

Timing and extent of pancreatic surgery (Table 1)

Two forms of presentation leading to surgery were seen—early and late—as previously described[4]. Four patients were admitted with fulminant necrotizing pancreatitis and deteriorated rapidly despite intensive care support including ventilation. In these patients, the interval between onset of acute pancreatitis and pancreatic surgery was 2 days, 4 days (two patients) and 14 days. In five patients, pancreatic surgery was carried out between 2 and 8 weeks after the onset of the attack. Two of these five patients had undergone surgery before their pancreatic resection. Patient 6 had had an attempted cystgastrostomy for what was thought to be a pseudocyst but which in reality was pancreatic necrosis and Patient 8 had undergone a cholecystectomy and exploration of the common bile duct for gallstone-associated pancreatitis. In neither case were rigid drains used which could have caused the colonic damage.

Six patients with pancreatic necrosis underwent sub-total pancreatic resection with removal of the body and tail of the gland[4]. Two patients, also with gland necrosis, had necrosectomy and one patient with a pancreatic abscess and necrosis underwent drainage of the abscess and distal pancreatectomy.

Table 1 *The timing and extent of pancreatic and colonic surgery in ten patients with severe acute pancreatitis who developed colonic complications.*

Patient	Age and sex		Ranson criteria (Ref. 5)	Aetiology	Pancreatic lesion	Pancreatic surgery	Site of colonic involvement	Colonic surgery	Outcome	Hospital stay (days)
1	26	M	6	Alcohol	Necrosis	Sub-total resection (day 2)	Splenic flexure	Resection with proximal colostomy + mucous fistula (day 21)	Died (day 23)	
2	32	M	3	Alcohol	Necrosis	Sub-total resection (day 4)	Splenic flexure	Resection with proximal colostomy + mucous fistula (day 18)	Survived	192
3	33	F	7	Gallstones	Necrosis	Necrosectomy (day 14)	Ascending colon	Right hemicolectomy (day 18)	Died (day 19)	
4	55	M	4	Alcohol	Necrosis	Sub-total resection (day 30)	Transverse colon	Resection with proximal colostomy + mucous fistula (day 30)	Survived	88
5	58	M	3	Idiopathic	Abscess	Drainage of abscess + distal pancreatectomy (day 16)	Transverse colon	Extended right hemicolectomy (day 16)	Survived	80
6	60	M	3	Alcohol	Necrosis	Necrosectomy (day 56)	Splenic flexure	Resection with proximal colostomy + mucous fistula (day 56)	Died (day 86)	
7	62	F	4	Post-operative	Necrosis	Sub-total resection (day 21)	Splenic flexure	Resection with proximal colostomy + mucous fistula (day 21)	Died (day 27)	
8	64	F	5	Gallstones	Necrosis	Sub-total resection (day 30)	Splenic flexure, descending colon	Resection with proximal colostomy + mucous fistula (day 30)	Survived	241
9	67	M	6	Gallstones + alcohol	Necrosis	Sub-total resection (day 4)	Transverse colon	Resection with proximal colostomy + mucous fistula (day 4)	Died (day 21)	
10	75	M	5	Gallstones + alcohol	Necrosis	—	Transverse colon, splenic flexure, descending colon	Sub-total colectomy (day 1)	Died (day 29)	

Day 1 = day of admission. The timing of surgery is shown in parentheses

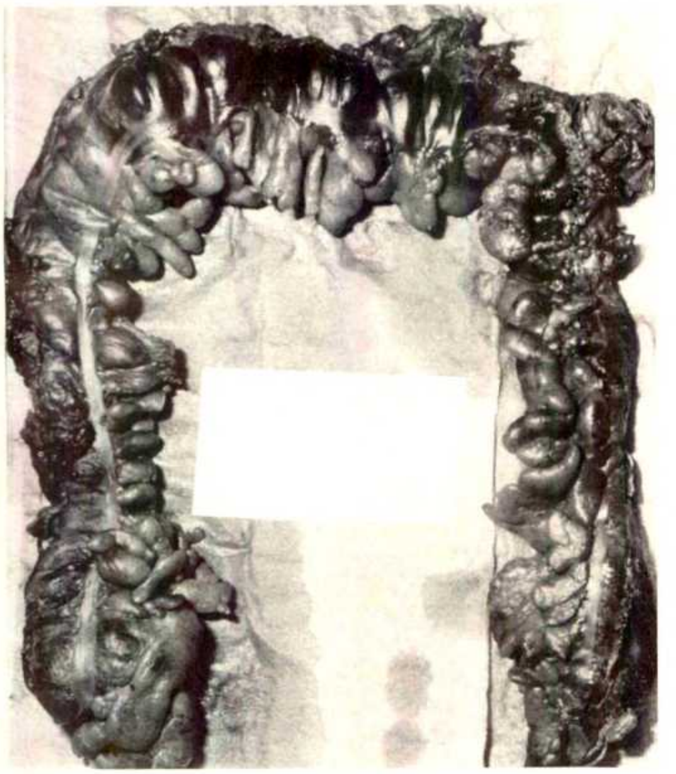

Figure 1 *Patient 10. At laparotomy this patient was found to have severe acute pancreatitis and infarction of the transverse colon, splenic flexure and descending colon. The abrupt demarcation between normal and infarcted colon is clearly seen in the region of the hepatic flexure*

Patient 10 did not undergo pancreatic surgery. This elderly man underwent emergency laparotomy for peritonitis at West Middlesex University Hospital. Severe haemorrhagic pancreatitis with infarction to the transverse colon, splenic flexure and descending colon (*Figure 1*) were unexpected findings. He underwent sub-total colectomy with formation of an ileostomy and distal mucous fistula and drains were inserted. Five days postoperatively he had a cerebrovascular accident which precluded further surgery.

Timing and extent of colonic surgery (Table 1)

In seven patients, colonic involvement was present at the time of pancreatic surgery or diagnostic laparotomy (Patient 10) but in three it presented between 4 and 19 days postoperatively. The indications for further surgery in these three patients were persistent abdominal sepsis in one and the appearance of faecal fluid from drains in the left upper quadrant in two.

In nine patients, the consultant surgeon in-charge (G.G. or H.A.F.D.) considered the colon to be non-viable and that resection was indicated (four patients having perforations at the splenic flexure). Patient 10 was operated on by M.C.A. while he was a senior registrar at West Middlesex University Hospital. At St. Mary's Hospital, operations were performed by the consultant in-charge (G.G. or H.A.F.D.) or by senior registrars under the guidance of one or other consultant.

The transverse colon alone was involved in three patients, the splenic flexure alone in four patients, the splenic flexure and descending colon in one patient, the ascending colon in one patient and almost the whole colon in one patient. All patients underwent colonic resection with the formation of either a proximal colostomy ($n = 7$) or ileostomy ($n = 3$) and distal mucous fistula.

Results

Colonic histology (Table 2)

In four patients the resected colon showed evidence of ischaemic

Table 2 *Colonic histology. A diagnosis of either 'pericolitis' or 'ischaemic necrosis' is given for each patient*

Patient	Site of vascular thrombosis	Evidence of ischaemia	Perforation	Serosa	Fat necrosis	Conclusion
1	—	—	+ (diverticulum)	Fibrosis, granulation tissue and acute peritonitis	—	Perforation of congenital diverticulum ? due to pericolic inflammation
2	—	Haemorrhage + congestion adjacent to perforation	+	Fibrosis and congestion with granulation tissue along perforation track	+	Pericolitis and secondary perforation
3	Small serosal vessels	A few inflammatory cells in the mucosa	—	Peritonitis, haemorrhage and granulation tissue	+ +	Mild ischaemic changes with serosal thrombi in an area of pericolitis
4	—	A few inflammatory cells in the mucosa	—	Fibrosis and congestion	+	Pericolitis and mild mucosal ischaemic changes
5	Mesentery (+ +)	Mucosal ischaemic changes and congested submucosa	—	Granulation tissue	+	Ischaemic necrosis
6	—	Haemorrhage + congestion adjacent to perforation	+	Congestion and granulation tissue along perforation track	+	Pericolitis
7	—	Early mucosal ischaemia and congested submucosa	—	Normal	—	Early ischaemic colitis
8	—	—	+ (diverticulum)	Acute inflammation and fibrous organization of granulation tissue	+	Perforated acquired diverticulum ? due to pericolic inflammation
9	Submucosa (+ +)	Full-thickness mucosal infarction	—	Fibrosis, congestion and granulation tissue	+ +	Ischaemic necrosis
10	Mesentery submucosa pericolic fat	Full-thickness mucosal infarction	—	Congestion + inflammation	+ +	Ischaemic necrosis

+, Present; + +, marked

damage (Patients 5, 7, 9 and 10). This ranged from very early superficial mucosal necrosis, epithelial cell sloughing, oedema and congestion of the lamina propria to full-thickness infarction (*Figure 2*). In the latter case (Patient 9) large submucosal vascular thrombi were seen in association with the infarcted area (*Figure 2*). In two cases, large vascular thrombi were also present in the mesentery and in this group areas of macroscopic 'fat necrosis' were in fact dead or infarcted fat as would be expected with a primary vascular cause. In these four cases, colonic necrosis most probably developed from inside to outside.

In six patients there was no evidence of mucosal or submucosal ischaemic damage in the resected colon, all changes being confined to the external layers of the colonic wall (Patients 1, 2, 3, 4, 6 and 8). In four patients (Patients 1, 2, 6 and 8) the colon contained a perforation which in two was through a diverticulum—congenital (in view of his age) in Patient 1 and acquired in Patient 8. In both there was serosal inflammation and organized peritonitis suggesting that the external inflammation secondary to acute pancreatitis may have precipitated the perforation. In neither case was there evidence of a primary diverticulitis. In the remaining two cases (Patients 2 and 6) there were abrupt changes at the mucosal surface from almost normal mucosa to the congested granulation tissue of the margin of the perforation track (*Figure 3*). In both specimens there was marked organization and fibrosis of the wall of the track extending to the serosal surface.

In two cases (Patients 3 and 4) the primary colonic damage was at the serosal surface and in the mesenteric/pericolic fat where fat necrosis, peritonitis, congestion, haemorrhage and some organization were seen. In Patient 4 there was evidence of ischaemic mucosal damage. In these six patients therefore, there was most likely spread of peripancreatic necrosis to involve the colonic wall from outside to inside.

Mortality

Six patients died between 1 and 30 days after colonic resection. The cause of death was overwhelming sepsis and multi-organ failure in five and massive retroperitoneal haemorrhage in one. In addition to sepsis and organ failure, Patient 10 also suffered a cerebrovascular accident which contributed to his death. Almost total necrosis of the pancreas was found at post mortem.

Of the four survivors, three have undergone successful colonic re-anastomosis and one (Patient 8) has refused further surgery and returned to her country of origin. The length of hospital stay in days for the four surviving patients (Patients 2, 4, 5 and 8) was 192, 88, 80 and 241 respectively.

Discussion

Colonic complications are believed to be rare in acute pancreatitis but the exact frequency is unknown. Twenty years ago Lukash[1] reviewed 100 patients with acute pancreatitis and found only one with a colonic lesion—an area of stenosis at the hepatic flexure on barium enema. Subsequently a number of authors have quoted an incidence of 1 per cent for this complication but clearly a larger sample size is required before the exact incidence can be determined.

The spectrum of colonic involvement in acute pancreatitis is broad. The commonest manifestation is probably colonic ileus which is seen on a plain abdominal X-ray as the 'colon cut-off sign' described by both Stuart[2] and Price[3]. It usually affects the splenic flexure and its incidence has been reported as between 1 and 14 per cent of all cases of pancreatitis[6–9]. The exact cause is unknown but it may be a visceral reflex mediated by the superior mesenteric plexus in the presence of retroperitoneal inflammation and/or transient colonic ischaemia[10].

The more serious forms of colonic involvement are: obstruction, necrosis, perforation and fistula formation. Colonic obstruction may occur from either extrinsic

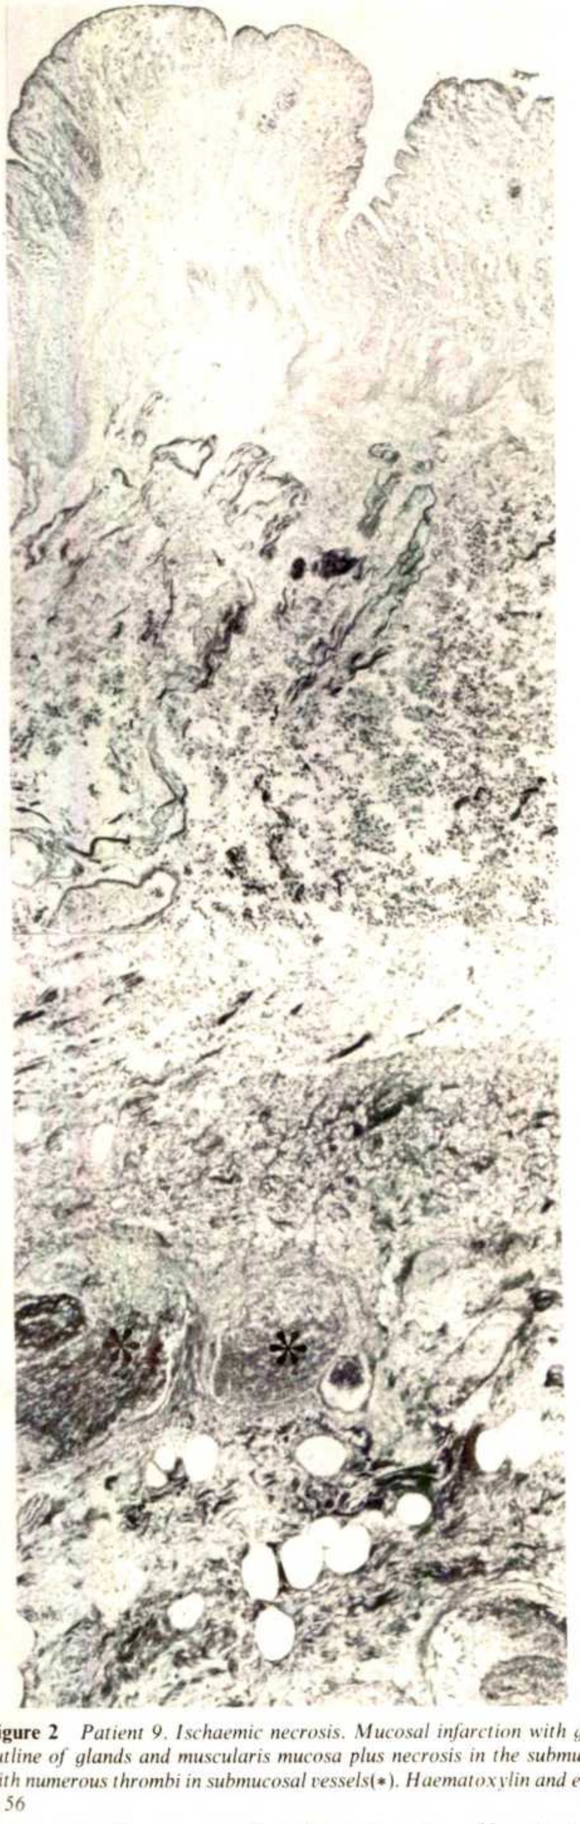

Figure 2 *Patient 9. Ischaemic necrosis. Mucosal infarction with ghost outline of glands and muscularis mucosa plus necrosis in the submucosa with numerous thrombi in submucosal vessels(*). Haematoxylin and eosin, ×56*

compression by a pancreatic inflammatory mass[11] or pericolic fibrosis. Colonic stenosis may present as large bowel obstruction during an attack of acute pancreatitis or some months later as a 'pseudocarcinoma' with rectal bleeding and an 'apple-core' lesion seen on barium enema. Seventy-eight cases have been reported in the world literature and in reviewing these Carboni and colleagues[10] noted that the site of stenosis was at the splenic flexure in 84 per cent. This area of the colon is at the watershed between the areas of supply of the middle and left colic arteries[12] and is often supplied by a poorly developed marginal artery[13]—facts which might suggest an ischaemic cause especially during periods of hypotension as occur in severe acute pancreatitis[14]. The splenic flexure, however, is also in close proximity to the tail of the pancreas and thus direct spread of enzyme-rich fluid, fat necrosis and peripancreatic inflammation to involve the colon may also be a significant causative factor[15].

The first report of colonic involvement in acute pancreatitis came from the USA in 1945 when Morton[16] described two patients, one with a pancreatic abscess and one with haemorrhagic pancreatitis, who both developed fistulae into the transverse colon and who both died from massive haemorrhage. In the same year, Moore and Castleman[17] reported a patient with pancreatitis who developed colonic infarction and inferior mesenteric vein thrombosis and died 63 h after the onset of symptoms.

In the past 22 years there have only been 36 cases of colonic necrosis and/or perforation reported in the world literature and our present account of ten patients now represents one of the largest series from a single centre. The frequency of this complication in our patients appears high. There may be several reasons for this. Firstly, we were operating on the most critically ill patients with severe acute pancreatitis—patients who were deteriorating and who, in many cases, were referred from other centres. In the past these patients may have been considered unsalvageable and would have died from abdominal sepsis with their colonic necrosis remaining unrecognized. Secondly, our aggressive policy of reoperation for continuing abdominal sepsis meant that the three postoperative colonic complications were detected. In one of these patients, the cause of the colonic perforation was almost certainly iatrogenic, being the result of erosion by a rigid abdominal drain. Thirdly, we developed a fairly low threshold for colonic resection after experience of this complication. This resulted in resection of the colon if its viability was in any doubt, a policy which, as will be discussed

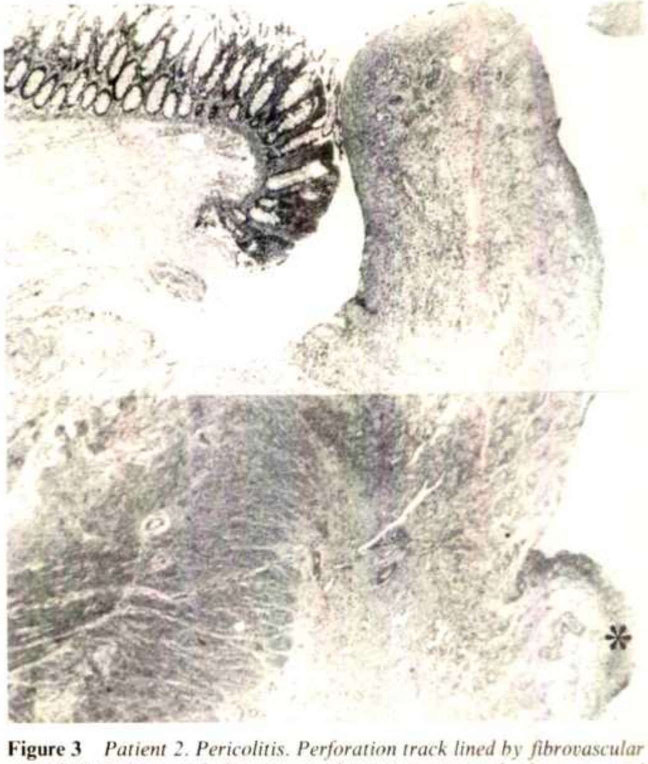

Figure 3 *Patient 2. Pericolitis. Perforation track lined by fibrovascular granulation tissue and showing on abrupt junction with almost normal mucosa. Thick granulation tissue(*) covers the serosal surface. Haematoxylin and eosin, ×35*

later, may have resulted in two patients undergoing unnecessary colonic resection. Such a conclusion is easily reached with hindsight. We are not alone, however, in finding a high incidence of this complication in patients with complicated severe acute pancreatitis. Pemberton and co-workers[18] have recently reported 16 patients with enteric fistulae among a group of 81 patients who underwent surgery for pancreatic abscess, making the comment that 'colocutaneous fistulae were particularly common'. Schein *et al.*[19] have reported three patients with pancreatic necrosis or abscess who developed colonic necrosis, all with alcoholic acute pancreatitis and all presenting within a 12-month period.

Analysis of the world series (*Table 3*) shows that: this complication is twice as common in men as it is in women; the median age affected is 48 years with a range from 14 to 86 years; the transverse colon and splenic flexure are by far the commonest sites involved; pancreatic necrosis and pancreatic abscess are equally responsible (see below); the overall mortality rate is 58 per cent. Pancreatic abscess is a somewhat incomplete descriptive phrase which is rarely defined and which is often used synonymously with pancreatic necrosis[36] thus making it likely that necrosis was the underlying pathological process within the gland in most of the cases described. The characteristics of our ten patients were similar to those in the world series: there was a predominance of men (M:F approximately 2:1); the transverse colon and splenic flexure were the commonest sites of involvement; pancreatic necrosis was the commonest underlying cause; the mortality rate was 60 per cent. Our patients, however, were slightly older with a median age of 59 years.

The colonic disorder was variable in the present series and ranged from the changes of 'pericolitis' through to ischaemic necrosis. This spectrum suggests two separate mechanisms of colonic damage. Firstly, direct spread of pancreatic enzymes and peripancreatic inflammatory tissue may involve the serosa of the colon and cause local inflammation and fat necrosis. The proximity of the tail of the pancreas to the splenic flexure has already been discussed in relation to colonic stenosis. Indeed there is sound anatomical support for the hypothesis of direct spread of inflammatory mediators as the reflections of the posterior parietal peritoneum which form the two layers of the transverse mesocolon provide a potential pathway (*Figure 4*). Secondly, thrombosis of mesenteric and submucosal vessels may lead to infarction of the mucosa and deeper layers and the possibility of associated fat infarction and necrosis. Features of both these mechanisms may be seen in some cases and it is possible that the potentially reversible changes of early or mild ischaemia had resolved in some of our patients by the time they came to surgery, leaving only the serosal reaction and fat necrosis.

The exact mechanism of vascular colonic ischaemia in acute pancreatitis is unknown but a number of hypotheses have been suggested. The first is that it may occur as a result of venous infarction by retrograde thrombosis of the superior mesenteric

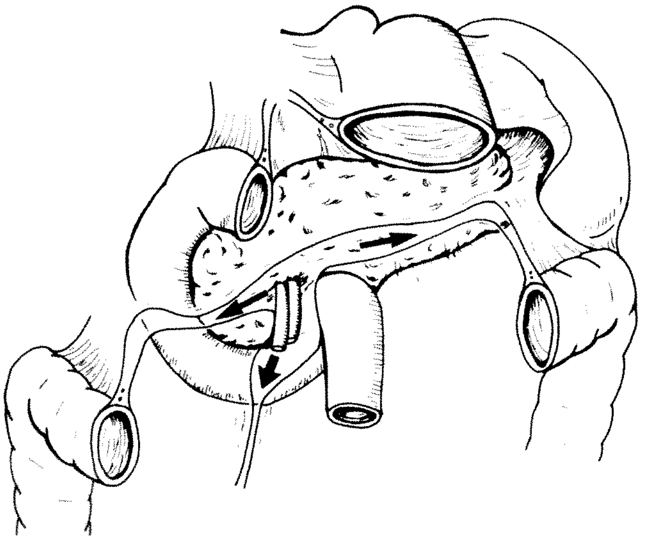

Figure 4 *The peritoneal reflections from the anterior surface of the pancreas provide a route for the spread of pancreatic enzymes and inflammatory products within the transverse mesocolon and the small bowel mesentery*

vein, starting in the splenic vein, as described by Moore and Castleman[17]. The second is that it may arise as a result of thrombosis of mesenteric vessels when oedema and inflammation within the transverse mesocolon result in compression of vessels with consequent slowing of blood flow which, together with systemic hypotension, may predispose to thrombosis. The third hypothesis is that coagulation abnormalities, in particular disseminated intravascular coagulation (which may occur in severe necrotizing pancreatitis[37]), may predispose to mucosal infarction[38]. The last is that sustained hypotension may lead to ischaemic damage and infarction of the colon particularly in an area such as the splenic flexure where the blood supply is often poor (see above). In addition, local pressure on the colon from an adjacent rigid drain may cause necrosis and lead to fistula formation or frank perforation as occurred in one of our patients.

The surgical management of patients with colonic involvement in severe acute pancreatitis remains difficult. The decision whether to resect the colon or not is based on surgical experience and few guidelines can be given. In each of the ten patients in this series, the surgeon considered that a colonic resection was necessary for either non-viability or perforation. On histological examination of the colon, however, only four showed ischaemic necrosis, the remaining six having pericolitis which had perforated in four. In retrospect, therefore, two patients may have undergone unnecessary colectomy. The natural history of pericolitis, however, is unknown in those in whom the colon is left *in situ*. It may be patients in this group who go on to develop a stricture and colonic stenosis if they survive their attack of pancreatitis.

A prospective study of patients with appendicitis has been conducted over a 3-year period in the Melanesian population of the North Solomons. Patients presented with suspected appendicitis at an annual rate of 39 per 100 000 population. Appendicitis was confirmed at operation at an annual rate of 22 per 100 000 population. The disease was considerably more frequent in male than in female patients. The annual appendicectomy rate was 29 per 100 000 population. Thirty per cent of patients presented with signs of late or complicated appendicitis, while 37 per cent of patients submitted to operation were found to have advanced appendicitis. The incidence and pattern of appendicitis in the North Solomons are quite different from those seen in the urbanized populations of developed countries.

Keywords: Appendicitis, appendicectomy, laparoscopy, incidence, disease pattern, Melanesia

The incidence and pattern of appendicitis in Melanesians have not been studied in detail or recorded in the literature. Clinical impressions among surgeons working in Papua New Guinea and the Pacific suggest that the condition is not uncommon and may be seen more frequently in semiurbanized Melanesians.

The North Solomons is an island province of Papua New Guinea with a population of around 140 000 Melanesians and 4000 expatriates. The province is served by a single general hospital where virtually all abdominal surgery is performed. This situation provides an ideal opportunity to study the disease in a relatively stable and homogeneous population.

Patients and methods

Records were kept prospectively from January 1983 to December 1985 on all Melanesian patients in the province presenting with suspected appendicitis or undergoing appendicectomy for other indications. Clinical presentation, investigations (including laparoscopy), operative findings and hospital mortality were recorded. Histological examination of specimens was performed by the Department of Anatomical Pathology at Prince Henry's Hospital, Melbourne, Australia.

Results

Over the 3-year period of the study 164 patients presented with clinically suspected appendicitis, giving an average annual incidence of 39 per 100 000 population. Cases proved at operation amounted to 22 per 100 000 population per annum (*Table 1*). Histological evidence of appendicitis was reported at an annual rate of 17 per 100 000 population. Total annual appendicectomy rate was 29 per 100 000 population.

The age distribution of patients presenting with appendicitis is recorded in *Figure 1*. The mean age of female patients at presentation was $22{\cdot}3 \pm 7{\cdot}5$ years and of male patients was $26{\cdot}7 \pm 10{\cdot}3$ years (±s.d.). The difference in mean ages is significant ($P < 0{\cdot}01$, Student's t test).

Late appendicitis was significantly more common in male patients (36 per cent) than in female patients (21 per cent) at presentation ($P < 0{\cdot}05$, χ^2 test, *Table 2*). Thirty-seven per cent of patients (males 42 per cent, females 22 per cent) submitted to operation were found to have complicated appendicitis (*Table 3*).

Appendicectomy was performed at an annual rate of 29 per 100 000 population (males 21 per 100 000 and females 8 per 100 000, *Table 1*). Most patients who underwent appendicectomy did so in the context of appendicitis or its complications. One patient required appendicectomy for technical reasons following exteriorization of an injured colon. The appendix was infrequently removed at operation for other conditions, i.e. '*en passant*'.

Histological examination was obtained in 86 per cent of the 123 appendices removed (*Table 4*). Fifteen specimens were discarded by one surgeon, while all other surgeons and registrars submitted appendices for pathological examination. The operative diagnosis of acute appendicitis was confirmed histologically in 93 per cent of specimens submitted, i.e. 7 per cent of histologically examined appendices considered at operation to be inflamed had no histological evidence of acute appendicitis. In addition, 6 per cent of appendices considered to be normal by the surgeon, and which were submitted to histology, in fact had histological evidence of acute inflammation.

There were no in-patient deaths in this study and all patients were considered to be progressing satisfactorily at discharge. No subsequent deaths have been notified, but detailed follow-up of all patients was not possible after discharge.

Discussion

The true incidence of appendicitis is difficult to document in any community[1,2]. The true incidence in the North Solomons may have been underestimated in this study as patients in remote areas with mild and self-limiting appendicitis probably do not attend the hospital. In addition, elderly patients with severe appendicitis may not seek surgical treatment and the cause of their death would not be determined as the post-mortem rate is low.

The annual incidence of appendicectomy is easier to ascertain, and in this study the annual rate of 29 per 100 000 population is low when compared with rates from developed countries such as the USA with a rate of about 140 per 100 000 population[3] and Australia with a rate of about 210 per 100 000 population[4].

This difference in appendicectomy rates almost certainly reflects a true difference in the incidence of the disease between the populations. The difference in incidence is perhaps even more striking when it is considered that 62 per cent of the Melanesian population is aged 24 years or less[5] and that appendicitis is a disease of the young[6]. The incidence of proven appendicitis in female patients is about one-third that in male patients (*Table 1*). This difference is significant ($P<0{\cdot}05$, χ^2 test) and is different from developed countries where most studies report only a slight male preponderance[7,8].

Forty-five per cent of patients came from rural areas and were mainly subsistence farmers. The remaining 55 per cent were semi-urbanized, living in small towns and consuming a mixed diet of traditional and 'western' foods. At the 1980 census[5], 85 per cent of the population were recorded as rural, thus appendicitis is much more common in urban Melanesians ($P<0{\cdot}05$, χ^2 test) and may be related to changes in diet or lifestyle[9,10].

The overall incidence of late appendicitis at presentation was high at around 30 per cent. In particular 42 per cent of male patients submitted to operation had advanced appendicitis (gangrene, perforation, abscess or generalized peritonitis) which is higher than the rates of 4–30 per cent published in series from Australia[7], the USA[11] and Denmark[8]. This high incidence seems to be due to delays before patients reach hospital.

Other operation	2 (2)	4 (6)
Total	101	63

Figures in parentheses are percentages

The clinical diagnosis of acute appendicitis is not easy or reliable, and studies show error rates of up to 30 per cent in male patients and 46 per cent in female patients aged less than 50 years[1,7,11,12]. Language and cultural differences are additional difficulties in the North Solomons. Like other workers[14], we have found laparoscopy to be of value in the diagnosis of appendicitis, especially in young women where 46 per cent of those presenting with suspected appendicitis underwent laparoscopy alone thus avoiding unnecessary appendicectomy (*Table 5*).

This prospective study documents the incidence of acute appendicitis in the Melanesian people of the North Solomons and confirms that the disease is much less common than in the white populations of developed countries. A higher incidence of appendicitis in semi-urbanized and in male Melanesians is also documented.

Acknowledgements

The authors would like to thank all the staff of the Department of Surgery, Arawa General Hospital and in addition Dawn Duncan for maintaining the appendicectomy register, Helen Lester and Chris Pennifold for secretarial assistance, Dr M. Drake and his colleagues for pathological examination and reporting on specimens, and Mr T. Callaghan for statistical advice.

High volume lesser sac lavage in acute necrotizing pancreatitis

**O. Teerenhovi,
I. Nordback and J. Eskola***

The effect of lesser sac drainage with or without lavage on some early predictors and on outcome in acute necrotizing pancreatitis was analysed. The evaluation was made prospectively for 24 patients, in a single centre study. According to Ranson's criteria and laparotomy findings, the lavage and drainage groups were comparable and the pancreatitis was severe and necrotizing in both groups. In a longitudinal analysis of the first 4 postoperative days, lavage did not show any advantage over drainage, as measured by seven prognostic signs (serum creatinine, blood glucose, base excess, haematocrit, white blood cells, C-reactive protein and immunoreactive phospholipase A_2 concentration). Furthermore, the study did not find that lavage had any positive effect on the incidence of mortality (36 versus 17 per cent in the drainage group) or on septic complications in acute necrotizing pancreatitis. In the total series the extent of pancreatic necrosis was an essential predictor of the outcome.

Keywords: Acute necrotizing pancreatitis, lesser sac lavage, prognostic signs, phospholipase A_2

The two basic problems in severe pancreatitis are early systemic complications due to toxaemia and late septic complications. One treatment method in pancreatitis is peritoneal lavage, which can be carried out non-operatively (by percutaneously placed catheters) or operatively. The treatment of acute necrotizing pancreatitis with peritoneal lavage is based on two supportive measures. It may reduce the amount of toxins present in ascitic fluid[1-3] and wash out peripancreatic debris[4,5]. Previous encouraging results showing early clinical improvement with non-operative lavage therapy[6,7] have not been confirmed in two recent prospective studies[8,9].

The present randomized prospective study in a single hospital was carried out to evaluate the outcome of operative lesser sac drainage with or without lavage in the treatment of acute necrotizing pancreatitis. The effects of this treatment on some selected reliable prognostic factors and on serum phospholipase A_2 concentration were also analysed.

Patients and methods

During the 3-year period from January 1985 to January 1988, 269 patients were admitted to Tampere University Central Hospital with the clinical diagnosis of acute pancreatitis. Our treatment protocol was as follows. The indication for urgent laparotomy was in all cases clinically defined peritonitis. Moreover seven patients had multiple organ failure while in four cases the diagnosis was uncertain. At laparotomy the pancreas was explored by dividing the gastrocolic ligament. In patients with the necrotizing form of acute pancreatitis (26 cases, 9·7 per cent) peripancreatic necrosis was opened by sharp dissection and deep exploration of the pancreas was performed. The necrosis was classified as deep if it extended into the pancreatic parenchyma for a depth of more than 0·5 cm. Two patients were withdrawn from the study because resection of the pancreas was undertaken for total parenchymal necrosis. In all cases with pancreatitis, cholangiography or choledochoscopy was performed and any gallstones were extracted. The biliary tract was intubated via T tube choledochostomy (16 cases) or cholecystostomy (eight cases), without postoperative complications. The peripancreatic drainage was performed with two silicon drains (9 mm inner diameter). One drain was placed from the right to lie close to the pancreatic head and the other from the left to lie behind the splenic flexure of colon close to the pancreatic body and tail. The gastrocolic ligament was not closed.

Thereafter, the 24 patients (8·9 per cent) were randomized to the postoperative lesser sac lavage group or to the drainage group, using the sealed envelope technique. To avoid sequestration of the lavage fluid in the 12 patients with postoperative lavage, a separate catheter (4 mm in diameter) was inserted through a small midline incision below the umbilicus, and was passed into the pelvis. All patients were treated postoperatively in a surgical intensive care unit.

Lesser sac lavage

The lavage fluid was a balanced electrolyte solution without antibiotic addition containing 13·6 mg/ml glucose (Dianeal®, Travenol Laboratories Ltd., Finland). One litre of fluid was infused into the lesser sac for about 15 min and then allowed to drain by gravity for about 45 min. Thus, the daily volume of infused fluid was 24 litres. It was intended to continue lavage for at least 7 days. The mean duration of lavage was, however, 6·9 days (range 4–12; excluding one death on the first day). In five patients the lavage was discontinued before the seventh day. In addition to the one early death, the cause of discontinuation (four patients) was retention of fluid in the abdominal cavity due to the obstruction of the drainage system despite prolongation of the outflow period. Hypertonic dialysate was not used.

Phospholipase A_2

All samples of serum were preserved at −70°C before enzyme assay. Immunoreactive phospholipase A_2 was measured using a time-resolved immunofluorometric assay described earlier[10] with slight modifications. Antiserum to human pancreatic phospholipase A_2 was raised in sheep and purified by immunoadsorption. Solid-phase antibodies were prepared by adsorption of the specific antibodies to the walls of polystyrene microtitration wells (Eflab Comany, Helsinki, Finland). Labelled antibodies were prepared with Eu^{3+}-N′-(*p*-isothiocyanatobenzyl)diethylenetriamine-N^1,N^2,N^3,N^3-tetraacetate[11]. The fluorescence was measured with a time-resolved fluorometer (1230 Arcus®, LKB-Wallac Company, Turku, Finland).

Patients

The patients in the two groups were well matched for clinical and laboratory signs (*Table 1*). Duration of symptoms before operation, operation duration, operative blood loss, volume of ascitic fluid and macroscopic necrosis of the pancreas also correlated well between the two groups (*Table 2*).

Student's *t* test and χ^2 test were used for statistical calculations. The data are expressed as mean ±s.d.

Results

Respiratory insufficiency

The incidences of postoperative artificial ventilation for the lavage and drainage groups were 83 and 67 per cent respectively, the duration of ventilatory support being 11·2 and 14·2 days respectively. During the first 4 postoperative days there was no significant difference in the severity of respiratory insufficiency

0007–1323/89/040370–04$3.00 © 1989 Butterworth & Co (Publishers) Ltd

between the lavage group (P_{a,O_2}:F_{i,O_2}, 163) and drainage group (P_{a,O_2}:F_{i,O_2}, 193).

Prognostic factors

Longitudinal analysis of six prognostic signs (serum creatinine, blood glucose, base excess, haematocrit, white blood cell count and C-creative protein) during the first 4 postoperative days did not reveal any significant benefits of lesser sac lavage over drainage alone (*Table 3*). Similarly, longitudinal determination of serum phospholipase A_2 concentration showed no differences between the two groups (*Figure 1*).

Fluid balance

Overall fluid retention in the lavage and drainage groups during the initial 4 days was 360 and 5690 ml respectively ($P<0·01$). The volume of nasogastric aspirate was correspondingly 2370 and 1400 ml. Consequently the need for intravenous albumin (4 per cent) replacement during this period amounted to 3540 and 2050 ml respectively.

Infective complications (Table 4)

Bacterial contamination of ascitic fluid and (possibly as a consequence of this) abscess formation was a more common finding in the lavage group than in the drainage group. The bacteria cultured from ascitic fluid, found on the sixth postoperative day on average, were composed of Gram-negative rods (45 per cent), Gram-positive cocci (45 per cent) and anaerobes (10 per cent). In total, bacterial contamination of ascitic fluid was found in 75 per cent of patients with deep pancreatic necrosis and in 60 per cent of those with superficial pancreatic necrosis.

The indications for reoperation were radiologically verified intra-abdominal abscess (computed tomography in two cases,

ultrasound in three cases) or clinically diagnosed intra-abdominal sepsis (five cases). The operative findings were pancreatic abscess (seven cases), other intra-abdominal abscess (one case) and extensive peripancreatic necrosis (three cases). Reoperation for peritonitis or pancreatic abscess was required more commonly in the lavage group. A pancreatocutaneous fistula developed in two patients in each group.

Hospitalization

There was no difference between the lavage and the drainage group in the duration of intensive care (18 *versus* 14 days) or of overall hospital stay (38 *versus* 30 days).

Mortality

When studying the effect of lavage on mortality rate the patient in the lavage group who died of early multiple organ failure on the day of operation was excluded.

Four patients died (36 per cent) in the lavage group and two (17 per cent) in the drainage group. In the total series, the mortality rate in patients with deep pancreatic necrosis was higher (5 of 8, 63 per cent) than in those with superficial necrosis (2 of 16, 13 per cent) ($P<0.01$). *Table 5* shows the mortality rate according to the depth of pancreatic necrosis in both groups According to clinical and autopsy findings the primary causes of death in the lavage group were. multiple organ failure due to septic complications 20 and 21 days after operation (two patients) and haemorrhages into the abdominal cavity 23 and 42 days after operation (two patients) In the drainage group one patient died following myocardial infarction on postoperative day 17 and the other following gastrointestinal haemorrhage on postoperative day 46.

Discussion

The multiorgan failure frequently found in conjunction with severe acute pancreatitis has been thought to be caused by activated pancreatic enzymes escaping into the circulation. Support for this hypothesis has been provided by studies on the ascitic fluid associated with acute pancreatitis. This fluid, which is rich in activated enzymes coupled with antiproteases[12], is very toxic both *in vivo* and *in vitro*[13,14]. Thus peritoneal lavage may be used in treating acute pancreatitis, to wash out toxins and prevent their harmful systemic effects. The results of several experimental[15–17] and clinical studies[6,7,18,19] are in accordance with this hypothesis. Peritoneal lavage has not been shown to reduce peripancreatic septic complications. Of the three previous prospective randomized controlled trials, only the first[7] concluded that peritoneal dialysis was advantageous in treating acute pancreatitis. The later studies showed no effects on mortality, major complications or on hospital stay[8,9].

Two methods of lavage therapy must be distinguished: peripancreatic lesser sac lavage through operatively-placed catheters, and peritoneal dialysis through percutaneously-inserted catheters The theoretical advantage of lesser sac lavage might be the evacuation of the toxins immediately after their secretion into the peripancreatic space before absorption into the circulation. In all three prospective randomized trials mentioned above, peritoneal dialysis was used instead of lesser sac lavage.

The results comparing peritoneal dialysis and lesser sac lavage are contradictory. In a retrospective analysis, Ranson and Spencer[6] found non-operative lavage to be superior to operative lavage, while Büchler *et al*[18] in a partly prospective trial preferred lesser sac lavage, combined in some cases with peritoneal lavage, to peritoneal lavage alone. Lesser sac drainage alone without lavage may also have some favourable influence on the course of acute pancreatitis[20,21] On this basis we designed a prospective randomized study which would investigate only the effect of lesser sac lavage on the course of acute necrotizing pancreatitis. The control patients had operative placement of lesser sac catheters, but did not undergo postoperative lavage

This study has the advantage of being performed in a single centre, but conversely it has the disadvantage of containing only a limited number of patients. In addition to the outcome of the patients we also analysed serum immunoreactive phospholipase A_2 concentrations and some accepted prognostic signs[22,23] for the first 4–6 days

Our results are mainly in accordance with previous prospective randomized studies We were unable to find a significant beneficial effect of lesser sac lavage on prognostic factors or on respiratory insufficiency. Contrary to previous analysis[6,18], we did not find that lesser sac lavage had a favourable influence on early mortality. This disagrees with Stone's prospective randomized trial[7] but agrees with two later studies[8,9]. The depth of the pancreatic necrosis was, however, the dominant prognostic factor in our study (*Table 5*) Moreover, in recent pathophysiological studies, Mayer *et al.*[24] have shown in experimentally induced canine pancreatitis that pancreatic enzymes mainly escape into the circulation via the peripancreatic veins and the lymphatic route, while peritoneal absorption is of minor importance. This is despite the fact that the majority of the enzymes released from the pancreas accumulate in ascitic fluid. Phospholipase A_2 has an essential role in the pathogenesis of acute pancreatitis[25] and its immunoreactive concentration in serum may reflect the severity of acute pancreatitis[26]. In our study, lesser sac lavage had no effect on serum immunoreactive phospholipase A_2 concentration. Normally a patient with severe pancreatitis is well-hydrated with a large third space In our series, lesser sac lavage did not decrease this initial fluid overload. In spite of the use of isotonic dialysate there was, however, less fluid sequestration during the early postoperative course of pancreatitis in the lavage group than in the drainage group. There was obviously a loss of protein in lavage fluid, bearing in mind the large plasma volumes given during the initial days of lavage therapy.

Pancreatic necrosis is often initially sterile[27] Opening the lesser sac can expose the necrotic pancreas to bacterial contamination, and this was also apparent in the present study. Lesser sac lavage did not prevent peripancreatic septic complications. The incidence of ascitic contamination and of abscess formation was particularly high. An explanation might be that the large volume saline wash-outs of the peritoneal cavity can be damaging to peritoneal macrophage function[28]

The present small series suggests that large volume lesser sac lavage does not have a beneficial effect on some early predictors or on the outcome of acute necrotizing pancreatitis.

Table 5 *Mortality rate and depth of pancreatic necrosis*

Mortality	Deep necrosis ($n=7$)	Superficial necrosis ($n=16$)

Mr E. W. Taylor

A prospective audit of 644 patients undergoing biliary tract operations has been conducted to assess the incidence of bile colonization and its association with the incidence of postoperative sepsis when all patients received the same prophylactic antibiotic. The accuracy of the determination of high-risk factors has been assessed as has the correlation between bile colonization and patients assessed as 'high risk'. Organisms were cultured from the bile of 121 (19 per cent) patients and among these the incidence of wound or intra-abdominal sepsis was 22 per cent whereas among patients with sterile bile the incidence was only 2 per cent ($P<0{\cdot}0001$)*. Although the incidence of bile colonization within the high-risk group (32 per cent) was more than twice that in the low-risk group (14 per cent), more than half (54 per cent) of the patients with positive bile cultures were in the low-risk group. It is concluded that, despite prophylactic antibiotics, bile colonization remains the major factor associated with postoperative sepsis, but that this cannot be predicted accurately by preoperative assessment of high-risk factors. Furthermore, we believe that a policy of selective administration of prophylactic antibiotics solely to high-risk patients cannot be justified.*

Keywords: Bile colonization, risk factors, prophylactic antibiotics, biliary surgery, postoperative sepsis

Patients undergoing biliary tract operations are at a higher risk of developing postoperative sepsis if bacteria are present in their bile at the time of operation[1–3]. Patients who are aged over 70 years, who have obstructive jaundice or common bile duct stones, and those operated on for acute cholecystitis, have an increased incidence of colonized bile[3–5]. The efficacy of antibiotic prophylaxis in these patients is now well established[6,7]. While some authors have concluded that antibiotic prophylaxis can be omitted in patients not fulfilling one of the above criteria[8,9], a recent report has shown that the association between high-risk factors and bile colonization may be less reliable than had been previously assumed[10]. Furthermore, it has been claimed that when prophylactic antibiotics are administered, the organisms responsible for wound infection are exogenous rather than those colonizing the bile[11–13].

An open prospective multicentre audit of patients undergoing biliary tract operations has been conducted to assess the incidence of bile colonization and its association with the incidence of postoperative sepsis when all patients received antibiotic prophylaxis. Ampicillin with sulbactam, a β-lactamase inhibitor, has been used as this combination has been shown to be effective against the organisms commonly isolated from bile cultures[14]. The high-risk factors assessed preoperatively have been compared with the findings at operation. The organisms isolated from the cultures of bile taken at operation have been compared with organisms isolated from postoperative wound infections to determine if the infection was of endogenous or exogenous origin when prophylactic antibiotics were used.

Study design

The value of prophylactic antibiotics in biliary tract surgery is now well established and we considered it unethical to use a placebo or no antibiotic control group to compare the incidence of sepsis. The incidence of infection, when prophylactic antibiotics are used, is generally reported in the range 5–10 per cent and to perform a study to demonstrate a clinically significant difference between two antibiotics in a statistically valid study of acceptable power would have necessitated the enrolment of several thousand patients. Therefore, we considered it more feasible to perform an open evaluation or audit of patients who received the same antibiotic. We sought to enrol 600 patients.

Patients and methods

The study was conducted by 25 consultant general surgeons in ten district general hospitals between May 1986 and October 1987. Patients undergoing operations on the biliary tract were eligible for entry. Patients were excluded if they were under 18 years of age, were pregnant or lactating, or if they had a history of penicillin allergy. Patients were also excluded if they had received antibiotic therapy within 48 h of operation. Ethical committee approval was obtained from each participating hospital and informed consent was obtained from all patients.

The history, clinical examination and preoperative investigations were recorded to assess the risk category. Patients were adjudged to be in the 'high risk' group if they satisfied one or more of the following criteria: age >70 years; the presence of stones or a benign stricture in the common bile duct, perioperative jaundice, carcinoma, emergency surgery (*Table 1*). No additional investigations were performed to improve the accuracy of this assessment.

On induction of anaesthesia all patients received ampicillin 2 g and

Values in parentheses are percentages, CBD, common bile duct

sulbactam 1 g intravenously. The biliary pathology was reviewed at laparotomy and any change from the preoperative diagnosis was noted Other intra-abdominal pathology, if present, was documented and the operation was performed in the usual manner of the individual surgeon

Bacterial swabs from the external nares were cultured preoperatively and at operation a specimen of bile was taken for culture from the gallbladder or from the common bile duct if this was opened Bile specimens were inoculated into Becton Dickinson Vacutainers® (Becton Dickinson, UK) (Columbia broth with sodium polyethanol sulphonate and increased cysteine, and supplemented peptone broth II) These were incubated for 24 h before being subcultured both aerobically and anaerobically

All patients were reviewed at 6 weeks Infection was defined as the discharge of pus from the wound or as a serous discharge from which bacteria were isolated presenting within 42 days of operation A clinical diagnosis of septicaemia and/or intra-abdominal infection was accepted as a failure of prophylaxis with or without bacteriological confirmation[15]

Statistical analyses were performed using the χ^2 test

Results

In all, 644 patients (164 men and 480 women) were entered with an age range of 19–90 years (mean 53·4). Only six operations were performed as emergencies (within 12 h of admission to hospital), 63 were performed on the next available operating list and 575 were performed as elective procedures.

Cholecystectomy was performed in 621 patients of whom 474 (76·3 per cent) had an operative cholangiogram performed. In 73 (11·7 per cent) exploration of the common bile duct was considered necessary. In 23 patients, either a previous cholecystectomy had been performed or the gallbladder was utilized in a biliary bypass procedure. The overall incidence of sepsis was 6·2 per cent. The incidence of sepsis after different operative procedures is shown in *Table 2*

Preoperatively 158 (24·5 per cent) patients had one or more of the high-risk factors (*Table 1*). At operation 20 patients were found to have stones in the common bile duct not diagnosed preoperatively. Conversely, four patients who had had common bile duct stones diagnosed preoperatively had no evidence of these stones on operative cholangiography. Thus the number of patients who had one or more of the high-risk factors increased to 177 (27·5 per cent) patients.

An organism was isolated from the bile in 121 (18·8 per cent) patients. The organisms isolated were predominantly bowel commensals (*Table 3*). Fifty-six (31·6 per cent) of the 177 patients in the high-risk group had colonized bile compared with 65 (13·9 per cent) of the 467 patients in the low-risk category ($\chi^2 = 26{\cdot}4$, $P < 0{\cdot}0001$).

Patients with colonized bile had an incidence of postoperative infection of 22·3 per cent and there was no significant difference between those in the high- and the low-risk groups (*Table 4*) By comparison, patients who had sterile bile had an overall incidence of sepsis of 2·5 per cent ($\chi^2 = 66{\cdot}3$, $P < 0{\cdot}0001$). In this group the incidence of sepsis in the high-risk category (4·1 per cent) was twice that in the low-risk group (2 0 per cent) but this difference did not reach statistical significance ($\chi^2 = 1{\cdot}76$, $P = 0{\cdot}18$). The correlation between patients with colonized bile and high-risk factors is shown in *Table 4*.

The organisms cultured from wound infections in patients with colonized bile ($n = 27$) were predominantly Gram-negative bacilli and the same organisms were isolated from the bile in 17 (63 per cent) of these patients. In six of the other ten patients, no wound culture was obtained and of the remaining four patients two had a *Staphylococcus aureus* wound infection which was of the same phage-type as the staphylococci isolated from their nares.

However, Gram-positive cocci were cultured from eight (62 per cent) of the 13 bacterial isolates from patients with infection who had sterile bile. Six patients had *S. aureus* wound infections where the same phage-type had been isolated from the nasal swabs and in three patients no wound culture was obtained. Coagulase-negative staphylococci were isolated from the wounds of two patients and an anaerobic coccus from the wound of one patient. In one patient *Clostridium perfringens* and *Escherichia coli* were isolated from both wound and intra-abdominal abscess and the patient subsequently died; this was the only death in the study. This patient underwent a cholecystectomy and the operative cholangiogram demonstrated a narrowing of the distal common bile duct. This was associated with a firm mass in the head of the pancreas and a diagnostic transduodenal Tru-Cut® (Travenol Laboratories Ltd , Illinois, USA) needle biopsy of the pancreas was performed. The biopsy was subsequently reported to be benign. Postoperatively the patient developed necrotizing pancreatitis and died. The bile culture at operation was sterile and *C perfringens* was cultured from the wound and from the pancreatic abscess cavity at repeat laparotomy.

Discussion

The incidence of bile colonization at operation has been reported to range from 16 to 47 per cent[1,9]. In this study we

have found an incidence of 18 8 per cent and the organisms we have isolated are those reported by most authors[8,11,16]. We have not isolated anaerobic organisms but these are not common in the biliary tract[17].

Postoperative infection was significantly more common in patients with positive bile cultures (22·3 per cent) than in those with sterile bile (2·5 per cent, $P<0·0001$) This degree of variation was found in both high- and low-risk groups. A similar result has been observed previously in patients undergoing biliary operations receiving cephalosporin antibiotic prophylaxis[12]. Although we observed a high incidence of infection in those patients with colonized bile our findings compare favourably with the 46 per cent incidence of postoperative septic complications reported by Chetlin and Elliott[3] in patients who had colonized bile and did not receive antibiotic prophylaxis.

Despite the comparatively minor degree of soiling of the peritoneum and wound by bile during surgery, the incidence of infection (22·3 per cent) is similar or greater than that reported after colorectal operations where one might anticipate a much greater degree of bacterial contamination of the operative field. Our results indicate that the soiling of the wound by colonized bile is the cause of sepsis and this raises the interesting problem of how many bacteria are necessary to cause sepsis. In this study, we have not attempted to quantify the number of bacteria in the bile nor the number contaminating the wound and peritoneal cavity. This problem has been assessed in colorectal operations[18] but similar work in biliary tract surgery does not appear to have been done.

The high incidence of postoperative infection in patients with colonized bile despite the use of prophylactic antibiotics is a matter of some concern. In a recent report in which jaundiced patients received tetracycline peritoneal lavage at the time of operation a much lower incidence of sepsis was observed[19]. It is possible that different surgical technique and the use of tetracycline are responsible for this variation. However, our results represent an audit of a number of surgeons rather than one team and we believe they are closer to the experience of most surgeons working in district general hospitals.

An alternative approach might be to attempt to render the bile sterile preoperatively in all patients by antibiotic therapy. However, there must remain doubt as to the efficacy of such a policy which could entail such side-effects as the development of antibiotic resistance or antibiotic-associated colitis.

It has been accepted that infections occurring after biliary tract operations are usually caused by biliary microorganisms[1,8,20]. However, these studies were conducted without antibiotic prophylaxis. When patients are given antibiotic prophylaxis, some authors have contended that postoperative infection may be exogenous in origin[11–13]. In 40 postoperative infections we have found endogenous organisms ($n=17$) to be slightly more common than exogenous ($n=14$). In nine patients with infection no culture was obtained as the infection presented after the patient had been discharged from hospital. Infections occurring in patients with colonized bile were predominantly of endogenous origin, the most common organisms being Gram-negative bacilli, notably *E coli* In contrast, patients with sterile bile who developed wound infections had a higher incidence of *S. aureus*

In this study only those investigations that the participating surgeon considered necessary to confirm the need for biliary tract operation were performed. Our protocol did not require that additional investigations be undertaken to improve the preoperative diagnosis of high-risk factors.

Review of the biliary pathology at operation revealed a preoperative underdiagnosis of common bile duct stones in four false positive and 20 false negative reports. Including these patients, the incidence of colonized bile in high-risk patients was 31 6 per cent, which compares with reported incidences of 39 per cent or greater in patients with similar pathology[3–5].

However, the incidence of bile colonization in low-risk patients in our series was 13·9 per cent which lies within the reported range of 8–19 per cent[4,11]. This confirms the view that a significant proportion of patients without any of the described high-risk factors may have colonized bile[10] and that the incidence of sepsis in this group cannot be neglected. While it could be argued that the incidence of colonized bile in this study is lower than that of previous reports owing to the effect of the antibiotic prophylaxis, previous work has suggested that antibiotics given immediately preoperatively do not sterilize the biliary tract[6,21].

The accurate identification of all patients with colonized bile continues to be difficult. Peroperative Gram staining of the bile has practical difficulties, may be misleading[22] and evidence suggests that antibiotic prophylaxis given after starting the operation is ineffective[23]. We have found a higher incidence of bile colonization in patients with one or more of the high-risk factors (31·6 per cent) than in patients with no risk factor (13·9 per cent). Patients over 70 years of age and those jaundiced at the time of operation were found to have a slightly higher incidence of bile colonization than those undergoing emergency operation or those with stones in the common bile duct.

A recent survey has shown a substantial increase in the number of surgeons using antibiotics prophylactically in biliary tract operations[24]. Whereas most surgeons now accept their use in all patients, there remains a substantial minority of surgeons who administer antibiotics only to patients whom they categorize as being at 'high risk'.

Our study demonstrates that bacterial colonization of bile is associated with a statistically increased risk of postoperative infection The categorization of patients into high- and low-risk groups does not accurately reflect bile colonization and on the basis of our results we believe that a selective policy of antibiotic prophylaxis cannot be justified.

The effects of interstitial delivery of low power (1·2–2 W), long exposure (600–1200 s) Nd YAG laser light on a transplantable fibrosarcoma in rats have been studied. Three cohorts of ten animals were treated either by 1·2 W for 600 s, 1·2 W for 1200 s or 2 W for 600 s to each tumour nodule. An additional untreated cohort served as controls and a further cohort was treated by radical surgical resection. A partial response as evidenced by ulceration was seen in all laser-treated tumours. In the cohort treated by 2 W for 600 s there was complete loss of palpable tumour, and in five out of the ten animals there was no evidence of local recurrence following a prolonged period of observation. Three of these eventually died from metastatic disease and two were cured. There was a significant prolongation of survival in this cohort compared with the controls (median 70 days versus 30 days, $P < 0{\cdot}05$), but not in any of the other cohorts. Histological assessment of tumours 2 days after laser treatment showed a central area of degeneration with shrunken and densely staining nuclei and disorganized cytoplasm, the boundary between the degenerate zone and surrounding viable tumour being well defined. The technique might be used to induce necrosis of intrahepatic and other solid organ tumours.

Keywords: Nd YAG laser, low power, interstitial, photocoagulation, fibrosarcoma

The use of heat for the destruction of tumours is ancient, the oldest reference being in *The Edwin Smith Surgical Papyrus*, which has been carbon dated to 1700 BC, in which the author describes the treatment of tumours on the breast using the glowing tip of a firedrill[1]. The ancient Greeks and Romans used heat widely as a therapeutic tool and its combination of haemostatic and tissue destroying properties was regarded as particularly valuable[2]. Hyperthermia, or the elevation of whole body or regional temperatures as a primary or adjuvant therapy for cancer, is based on the original observation of Busch in 1866[3] that a histologically proved facial sarcoma completely disappeared after two attacks of erysipelas associated with high fever. Coley in 1893[4] deliberately induced pyrexial states in cancer patients by injecting a toxin consisting of a filtrate from cultured haemolytic *Streptococcus* and *Bacillus prodigiosus*. To reduce the risks of hyperthermia attempts have been made to localize it to the site of the tumour. For deep tissues a variety of non-invasive techniques have been used including radiofrequency current, microwaves and ultrasound. Unfortunately, each has its limitations[5].

Soon after the first description of the ruby laser[6] reports appeared on the use of lasers to treat experimental tumours[7,8]. The ability to transmit laser light along thin, flexible optical fibres has allowed endoscopic delivery of laser light to the gastrointestinal tract and bronchial tree, and the principal use of lasers in the management of cancers has been for recanalization of obstructing lesions at these sites[9–12]. The standard technique is to hold the laser fibre about 1 cm above the tumour and deliver short bursts (0·5–2 s) of high power (50–80 W) Nd YAG laser light into the tumour. Repeated shots vaporize superficial tumour and coagulate deeper tissues. This relatively crude technique can only be used for tumours in hollow organs which are endoscopically accessible, and not for solid organ tumours.

We have recently described a technique for producing necrosis within solid organs using the Nd YAG laser[13]. This involves using very low power settings, of the order of 1–2 W, and long exposure durations (200–1000 s), with the laser fibre inserted into the tissue (interstitial placement). This produces a more gentle heating of tissue which in rat liver produces predictable, well defined necrotic lesions up to 16 mm in diameter. We present here the results of a survival study in rats transplanted with an aggressive fibrosarcoma which was treated using this technique.

Materials and methods

Fifty CBH rats (140–210 g) were transplanted with fibrosarcoma HSN/TC/7. Transplantation was by removing solid tumour (1 g) immediately after the death of the donor animal, and mechanically disaggregating it in a laboratory mixer/emulsifier (Silverson Machines Ltd Chobham, UK) at medium speed in 10 ml normal saline. The solution (0·1 ml) was injected subcutaneously into the flanks of the anaesthetized rats. Further sequential transplantations were undertaken to maintain the tumour line. Tumours grow rapidly to produce a contiguous row of 2–4 tumour nodules 1–1·5 cm in diameter within 21 days.

When the tumour nodules were between 1 and 1·5 cm in diameter, animals were allocated to one of five different treatment cohorts with ten in each cohort. Cohort 1 were controls and did not receive any therapy. Cohorts 2–4 were treated by low power interstitial (LPI) laser therapy. The laser used was a continuous wave Nd YAG laser (Model 212, CVI, Albuquerque, New Mexico, USA) producing invisible infrared light with a wavelength of 1064 nm. The laser light was focused on to the proximal end and transmitted along a 400 μm diameter quartz fibre. A 500 mW helium neon laser aligned coaxially with the Nd YAG laser provided a visible red aiming beam. For treatment the rats were anaesthetized using intramuscular fentanyl citrate and fluanisone (Hypnorm® Janssen Pharmaceuticals Ltd, Oxford, UK). The skin overlying the tumour was penetrated by a 19 G needle through which the laser fibre was passed into the centre of the tumour nodule. Exact positioning of the laser fibre was assisted by ensuring that the aiming beam produced its diffuse glow in the centre of the nodule. Each nodule of tumour within each rat was treated by a separate exposure to laser light. For cohort 2 this was with 1·2 W for 600 s, for cohort 3 with 1·2 W for 1200 s and cohort 4 with 2 W for 600 s. Cohort 5 received radical surgical excision of the tumour, including abdominal wall if necessary.

After treatment each animal was separately caged and received a standard laboratory diet. Each was weighed twice weekly. The dimensions of any residual or recurrent tumour mass and of any ulceration following therapy was also measured twice weekly. The approximate tumour volume was calculated from these measurements

0007–1323/89/040378–04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

by assuming that the tumour was cylindrical. Any animal in which the tumour reached 6 cm in length or 3 cm in breadth was killed as tumours of this size caused difficulty with walking. Animals which died without evidence of local recurrence underwent autopsy

Ten additional animals treated by LPI laser photocoagulation were killed 2 days later to assess tumour histology. Evans' blue was injected intravenously before killing. This dye is taken up by viable but not necrotic tumour and facilitates macroscopic determination of the amount of necrosis. Histological sections were prepared using a haematoxylin and eosin stain.

Statistical comparisons were made using the Student's *t* test or the Wilcoxon rank sum test when appropriate.

Results

In the control group the fibrosarcoma grew rapidly and all animals, having fulfilled the criterion for tumour size, were killed 25–35 days (median 30 days) after transplantation. Median tumour volume doubling time calculated from individual tumour volume–time curves in the 10 days before killing was 3·7 days. This rapid rate of tumour growth was paralleled by a median increase in weight of 1·5 g/day during this period, compared with a rate of 0·5 g/day in non-transplanted animals of similar age in our laboratory. No spontaneous ulceration of control tumours occurred.

In cohorts 2–4 all animals had some response to LPI laser therapy as evidenced by superficial sloughing and the development of an ulcer over the tumour 2–5 days after treatment. The mean change in tumour volume in these cohorts in the 3 days after laser therapy is compared with the control group in *Figure 1*. In the three laser-treated cohorts the change in tumour volume was significantly lower than in the controls. *Figure 2* shows changes in the mean weights of animals over the same time period, and these reflected the changes in tumour volume. The proportions of animals in cohorts 1–4 which, following therapy, had decreases in tumour volume, decreases in weight, complete loss of palpable tumour, lack of local recurrence and complete cures are shown in *Table 1*. Complete cures were defined as survival of the animal for 150 days after transplantation without evidence of tumour recurrence. Of the three animals in cohort 4 which died spontaneously without evidence of local recurrence, at autopsy two had pulmonary metastases and one had intra-abdominal metastases. In those animals without local recurrence the ulcer healed with scarring.

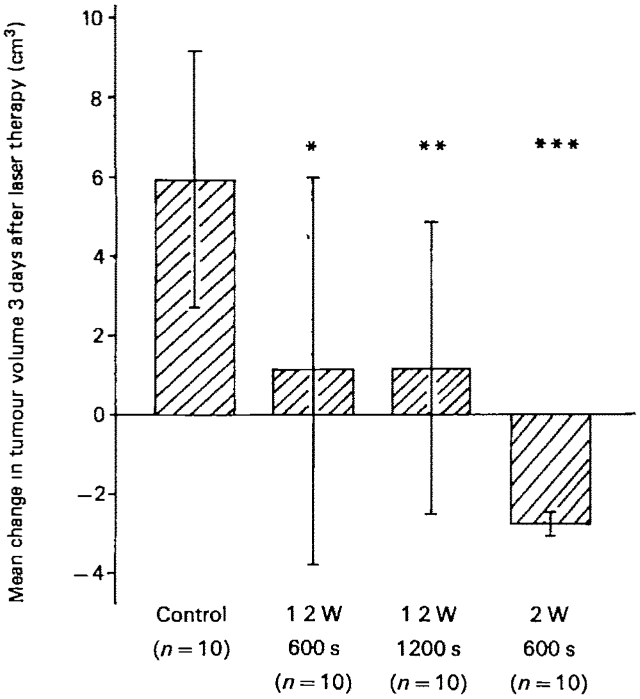

Figure 1 *Mean change (+s d) in tumour volume 3 days after laser therapy Significance values refer to comparisons with the control group* $^{*}P<0{\cdot}02$, $^{**}P<0{\cdot}01$, $^{***}P<0{\cdot}001$

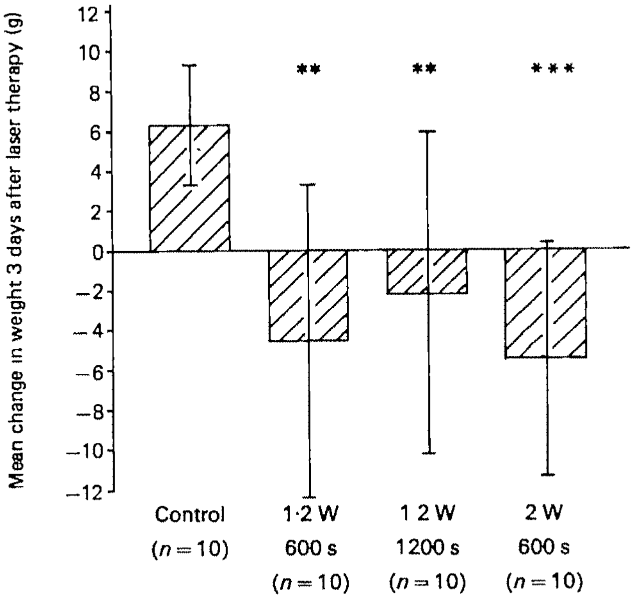

Figure 2 *Mean change (+s.d.) in animal weight 3 days after laser therapy. Significance values refer to comparisons with the control group* $^{**}P<0{\cdot}01$, $^{***}P<0{\cdot}001$

In cohort 5 (the surgical cohort), five animals died within 14 days of surgery, presumably as a consequence of it, as no recurrent tumour was apparent. Four were killed because of a large recurrent tumour 28 days after surgery and one animal was cured. Overall survival from the day of transplantation is shown for all five cohorts in *Figure 3*. Cohort 4 showed significantly prolonged survival compared with the control group but there were no other significant differences in this regard between any of the other groups.

Histological examination of tumours in animals killed 2 days after LPI laser therapy showed a central area of degeneration in which cell nuclei had become shrunken and densely staining and cytoplasm was disorganized. There was a well defined boundary between this degenerate zone and surrounding viable tumour with little evidence of any inflammatory response in the boundary. Histological examination of tumours in animals killed more than 2 days after treatment was not practicable as they simply consisted of a mass of sloughing debris.

Discussion

This study has demonstrated that it is possible to produce necrosis of transplanted fibrosarcomas in rats by prolonged interstitial exposure to low power Nd YAG laser light The best results were obtained in the rats of cohort 4 in which each nodule of tumour was treated with 2 W for 600 s. Using these parameters, all ten animals treated had complete loss of palpable tumour. In five there was no evidence of local recurrence and, although three of these animals died from metastatic disease, two were cured. Animals in this cohort had a significantly prolonged survival compared with those in the control cohort and there was a trend towards a prolonged survival compared with the others. The choices of power and exposure duration were based on a study of the effects of this technique in normal liver[13] which showed that, for a given quantity of energy, the extent of necrosis increased with increasing power with a plateau effect above 1 W and, for a given power setting, increased with increasing total energy with a plateau between 600 and 1000 J Liver and fibrosarcoma have different optical properties and optimal parameters in liver are unlikely to be optimal in fibrosarcoma. It is possible that although 2 W for 600 s produced the best results in this study, other combinations of power and exposure duration could product superior results.

Temperature estimations using microthermocouple arrays close to a laser fibre tip emitting 2 W in liver[13] have shown

Table 1 *The numbers of animals with ulceration over the tumour, decreases in tumour volume, decreases in animal weight, complete loss of palpable tumour, lack of local recurrence and complete cure following low power interstitial Nd YAG laser therapy*

	Cohort 1 Controls ($n = 10$)	Cohort 2 1·2 W, 600 s ($n = 10$)	Cohort 3 1·2 W, 1200 s ($n = 10$)	Cohort 4 2 W, 600 s ($n = 10$)
Ulceration over tumour (n)	0	10	10	10
Decrease in tumour volume (n)	0	5	4	10
Decrease in animal weight (n)	0	6	4	9
Complete loss of palpable tumour (n)	0	3	4	10
Absence of local recurrence (n)	0	0	0	5
Cures (n)	0	0	0	2

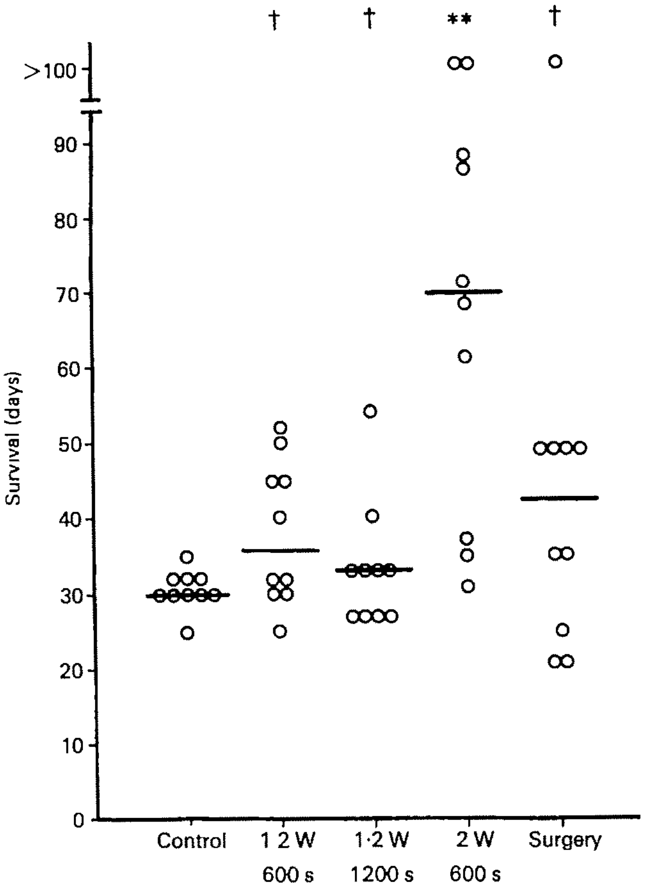

Figure 3 *Duration of survival of treated and untreated CBH rats from time of transplantation with fibrosarcoma. Horizontal bars denote median duration of survival. Significance values refer to comparisons with the control group* ** $P < 0·01$, † *n.s.*

temperatures up to 100 °C at the tip with a fairly rapid fall off to 50 °C 8 mm away. Combinations of temperature and time sufficient to produce necrosis were consistent with a purely thermal effect and not a specific effect of laser light. Histological changes in the fibrosarcoma were analogous to those found in liver in that there was a well defined demarcation between necrosing and viable tissue with the early changes of shrunken, darkly staining nuclei in the affected area and degeneration of the cytoplasm. Whereas liver healed by granulation and fibrous replacement of the necrotic area, the necrotic part of the fibrosarcoma completely sloughed off.

This particular tumour model was chosen because it was a convenient means of rapidly producing a single accessible tumour in rats on which survival studies could be performed. The technique has also been used on chemically induced colorectal adenocarcinomas in rats, a model which more closely approximates a human tumour[14]. Using this model it was possible to treat and destroy all colonoscopically accessible tumours. It was not possible to perform survival studies because with this model tumours develop along the whole length of the bowel. The present study has demonstrated that local tumour can be completely destroyed without recurrence during a prolonged period of observation.

A variety of invasive and non-invasive techniques have been used to produce local hyperthermia of tumours. Radiofrequency current, microwaves and ultrasound are all non-invasive but there are major limitations to their use[5,15]. In the cases of radiofrequency current and microwaves: they are absorbed by water-containing tissues and this may cause problems in tissues containing or surrounded by fluid, their depth of dose is limited to a few centimetres unless multiple applicators are used, the fat near the fat–muscle interface may overheat due to reflections, and they may interfere with metal temperature measuring devices. Ultrasound waves are highly absorbed by bone, causing bone heating and, because they are not transmitted through air cavities, they cannot be used in the lung or abdomen. Invasive techniques which have been described include the implantation of electrodes or thermoseeds which are then exposed to a magnetic induction field[16]. These require surgical placement and a further surgical procedure to remove them unless a foreign body is to be left. Microwaves can also be delivered directly to the tumour site via an applicator inserted into the tissue[17]. The applicator is larger than a typical optical fibre for interstitial laser therapy and the amount of necrosis produced per exposure appears to be less.

A technique which has some similarities to LPI Nd YAG laser therapy is photodynamic therapy (PDT)[18,19]. This involves systemic administration of a photosensitive dye which is taken up with some degree of selectivity by malignant tumours. When the dye is illuminated with light of a particular wavelength, a local cytotoxic effect is produced mainly on the tumour vasculature which causes local tumour necrosis. The light is conveniently produced by a dye laser which can be tuned to produce the appropriate wavelength and it can also be delivered interstitially. The degree of selectivity between tumours and adjacent normal tissue is not great but, with careful adjustment of the treatment parameters, it can be exploited to give some degree of selectivity[20]. There are a number of advantages of LPI Nd YAG laser therapy compared with PDT: no photosensitizer is used and the side-effect of generalized photosensitization is thus avoided; large blood vessels in the treated area are occluded during therapy[13] and bleeding as the tumour sloughs off is not seen as in photodynamic therapy; and infrared light from the Nd YAG laser penetrates tissue more deeply than the visible red light used in PDT[21] so larger volumes of tumour may be treated with a single exposure.

The principal attraction of LPI Nd YAG laser therapy is that laser light can be delivered to the required site via narrow diameter flexible optical fibres without the need for the administration of potentially harmful photosensitizing dyes. Using this technique it may prove possible to treat tumours within solid organs such as liver[22] or pancreas[23] in a relatively atraumatic fashion either percutaneously under ultrasound guidance, or at laparoscopy or laparotomy. Large tumours could be treated by multiple insertions of the laser fibre or by activating multiple fibres simultaneously. The technique is being further studied in larger animal models to assess its likely safety and efficacy in human tumours[24].

Positioning the Verres needle

S. P. Gupta

Unit III, RNT Medical College and Hospital,
Udaipur-313001, India
Correspondence to· Dr S. P. Gupta

During laparoscopy, pneumoperitoneum is achieved by inserting a Verres needle into the peritoneal cavity, before insertion of the trocar and cannula. It is sometimes difficult to judge whether the tip of the needle is in the peritoneal cavity.

The author has observed that when the needle tip has reached the peritoneal cavity, if the abdominal wall is lifted (preferably with both hands) below the umbilicus and the surgeon's ear kept close to the hub of the Verres needle, a hissing sound can be heard. This may be a distinct clear sound that can be heard from a distance or it may be only feebly audible with the ear close to the needle If such a sound is heard, it has been found to be a reliable sign that the needle tip is in the peritoneal cavity.

If no sound is heard, the needle tip is most probably extraperitoneal, the exceptions being when the needle tip is intraperitoneal but its opening is blocked by omentum, or when the needle has penetrated a viscus or blood vessel.

The author has found this sign helpful in many doubtful cases, especially in the obese patient. It has been used in 2000 cases and has invariably been proved to be reliable.

Wheeless[1] described a needle test using saline applied to the hub of the needle and Tamaskar[2] has described a technique in which 1 per cent xylocaine or distilled water is placed inside the needle and the abdominal wall is pulled up with the help of skin clips. The drop of liquid on the top of the needle is sucked into the peritoneal cavity if the needle tip is free and correctly sited in the peritoneum. However, the author has not found the sign described here previously noted in the literature.

A unifying pathophysiological hypothesis states that the plasminogen activating activity (PAA) of the peritoneal mesothelium determines whether the fibrin which forms after peritoneal injury is either lysed or organized into permanent fibrous adhesions. The PAA of human peritoneal biopsies was measured using a fibrin plate lysis technique to assess the changes that occur in inflammation and ischaemia, conditions which both produce fibrous adhesions. Activity was found in all biopsies from normal parietal and visceral (appendix, bowel and omentum) peritoneum with no significant site-to-site variation. Inflamed peritoneum (parietal, appendicular and mesenteric) had significantly less PAA compared with normal peritoneum; visceral ischaemia also resulted in a significant decrease of PAA. These reductions in human peritoneal PAA observed in inflammation and ischaemia support the view that mesothelial PAA plays a key part in the prevention of events leading to the production of fibrous adhesions.

Keywords: Peritoneum, adhesions, plasminogen activators

Intraperitoneal adhesions form in the majority of patients following abdominal surgery[1] and also occur after other causes of peritoneal inflammation[1,2]. They account for 25–33 per cent of all cases of intestinal obstruction in developed countries[3] and are the commonest cause of small bowel obstruction[4]. In addition, intraperitoneal adhesions make subsequent abdominal operation more difficult and potentially hazardous.

An inflammatory exudate forms following peritoneal injury and leads to the deposition of fibrin in the peritoneal cavity[5]. All abdominal surgeons are familiar with the delicate strands of fibrin that are termed fibrinous adhesions. These are either lysed by the plasminogen–plasmin cascade or become organized to form permanent fibrous adhesions[6,7,20]. Studies in animals have shown that normal peritoneum possesses plasminogen activating activity (PAA) and that a reduction in peritoneal PAA occurs after direct injury, grafting or excision[6,8,9]. Such peritoneal insults are also associated with the development of adhesions. Although PAA has been investigated in a number of normal and neoplastic human tissues[10,11], there has been little study of human peritoneal PAA with or without concomitant injury or insult[8].

The aim of this study was to measure the PAA of normal human peritoneum and to assess the effect of inflammation and ischaemia on this activity.

Patients and methods

Patients

Peritoneal biopsies were taken from patients undergoing abdominal surgery. Patient details, operative findings and the sites of biopsy were recorded. Patients gave informed consent to inclusion in this study, which was approved by the local ethical committee.

Biopsy technique

Peritoneal biopsies were taken using a disposable, 6 mm diameter biopsy punch (Stiefel Laboratories (UK) Ltd, Wooburn Green, UK). Excessive tension on the peritoneum at the time of biopsy was avoided. All biopsies were obtained as soon as possible after the peritoneal cavity had been opened. Parietal peritoneal biopsies were taken close to the wound edge. Visceral peritoneal biopsies were taken only from tissue that was to be subsequently excised. After the peritoneum had been incised with the biopsy punch, the disc of peritoneum was carefully dissected off the underlying tissues, wrapped in aluminium foil and frozen in dry ice before transfer to a freezer at −80 °C. Whenever possible, paired biopsies were taken from adjacent areas of peritoneum.

Plasminogen activator extraction and assay

Plasminogen activator was extracted from all biopsies and assayed within 4 weeks. The peritoneal biopsies were thawed rapidly at room temperature and weighed. Each biopsy was washed with 0·5 ml rinsing solution (5 mM sodium dihydrogen phosphate, 0·15 M sodium chloride, pH 7·4) and placed into 1 ml homogenizing solution (2·5 mM sodium dihydrogen phosphate, 0·075 M sodium chloride, 0·25 per cent Triton X100 Sigma Chemical Co. Ltd., UK, pH 7·8) in a small plastic tube on ice. The tissues were then homogenized using an Ultra-Turrax (Janke and Kunzel, FRG) homogenizer for 30 s. The homogenates were centrifuged at 12 000*g* for 20 min at 4°C. Aliquots of 0·25 ml of supernatant were stored at −20°C until PAA assay.

PAA in the peritoneal tissue extracts was assayed using a standard fibrin plate technique[12]. A layer of fibrin was produced in the base of 5 cm diameter plastic Petri dishes (Sterlin Ltd., UK) by pouring in a solution containing 0·9 ml buffer (0·03 M sodium acetate, 0·03 M sodium barbitone, 0·02 M hydrochloric acid; pH 7·4), 3 ml of 1 per cent human fibrinogen (KabiVitrum Ltd., Stockholm, Sweden), 0·3 ml human plasminogen (KabiVitrum Ltd., 2·5 units/ml) and 0·2 ml bovine thrombin (Armour Pharmaceutical Co., USA, 20 units/ml). After the fibrin solution had set, a 6 mm diameter well was cut in the centre of the plate. The peritoneal tissue homogenates were brought to room temperature and 20 μl of each specimen was placed in the central well of a fibrin plate. Standard solutions using human urokinase (Sigma Chemical Co. Ltd.,) reconstituted in sterile water were placed on fibrin plates at the time of each batch of assays.

All plates were then incubated at 37 °C for 24 h and the diameter of the zone of lysis around the central well was measured directly by placing the plates on top of a measuring scale. The maximum and minimum diameters were recorded and the mean value used. A standard plot of diameter of fibrin plate lysis against log urokinase was constructed for each assay and the line of best fit calculated using least squares regression analysis. For paired adjacent peritoneal biopsies the mean PAA level was calculated. Lysis did not occur in any assay with the homogenizing mixture alone. Plate lysis was abolished by prior heating at 80 °C for 20 min, confirming that fibrinolysis was mediated through plasminogen. The results for fibrinolysis were expressed in Ploug units of urokinase per square centimetre of peritoneum (PU/cm^2). The lower limit of sensitivity of the assay was 0·9 PU/cm^2. The coefficient of variation of the PAA-assay was 9 per cent.

0007-1323/89/040382-03$3.00 © 1989 Butterworth & Co (Publishers) Ltd

Statistical methods

The Mann–Whitney U test was used for comparisons between groups

Results

PAA was identified within the range of this assay system for 271 of 309 (88 per cent) peritoneal biopsies assayed. The Spearman rank coefficient of correlation for PAA measured in paired biopsies taken from adjacent areas of peritoneum was 0·8 ($P < 0·0001$, $n = 140$ pairs). Similar levels of PAA were found in peritoneal biopsies taken from normal parietal peritoneum (median 4·4 PU/cm^2, range 2·5–11·5, $n = 22$), inguinal hernial sac (median 3·2 PU/cm^2, range <0·9–10·3, $n = 11$), normal omentum (median 4·4 PU/cm^2, range 1·6–13·8, $n = 11$), normal appendix (median 6·9 PU/cm^2, range 1·9–14·3, $n = 7$) and normal bowel (median 5·1 PU/cm^2, range 1·8–6·0, $n = 6$). These PAAs were similar to those obtained in endothelial biopsies taken from the long saphenous vein (median 5·6 PU/cm^2, range 4·6–8·0, $n = 4$). There was no significant correlation between the PAA in biopsies of normal peritoneum taken from different sites in the same patients: parietal and omental ($n = 11$), parietal and visceral ($n = 10$) or omental and visceral ($n = 6$).

The peritoneal PAA was lower in biopsies taken from inflamed parietal peritoneum (*Figure 1*). Inflammation in this group was secondary to appendicitis ($n = 4$), perforated duodenal ulcer ($n = 2$), acute cholecystitis ($n = 2$), strangulated small bowel secondary to adhesion obstruction ($n = 2$) and colonic diverticulitis ($n = 1$). A similar reduction in peritoneal PAA was seen in patients with acute appendicitis, both in the appendix serosa (*Figure 2*) and in biopsies taken from the appendix mesentery (normal mesentery: median 5·4 PU/cm^2, range 2·8–11·9, $n = 5$; inflamed appendix mesentery: median 1·7 PU/cm^2, range <0·9–3·2, $n = 8$, $P < 0·01$).

No difference in PAA was detected between patients with peritoneal inflammation who had positive bacteriological cultures obtained from the abdominal cavity and those who did not.

Five patients had biopsies taken from ischaemic visceral peritoneum (two colon, two appendices epiploicae and one small bowel) and the PAA of these biopsies was lower than normal parietal, intestinal or omental biopsies (*Figure 3*).

Discussion

There are many causes of intra-abdominal adhesions, but the importance of tissue ischaemia has received much attention[3]. While ischaemia is a powerful stimulus to adhesion formation, it does not explain those adhesions observed following other peritoneal insults such as chemical or physical injury and bacterial peritonitis. A unifying pathophysiological mechanism for adhesion formation is provided by the hypothesis that the level of PAA of the peritoneal mesothelium (or other exposed tissue surface) determines the course of inflammation towards fibrinolysis or organization[6,7].

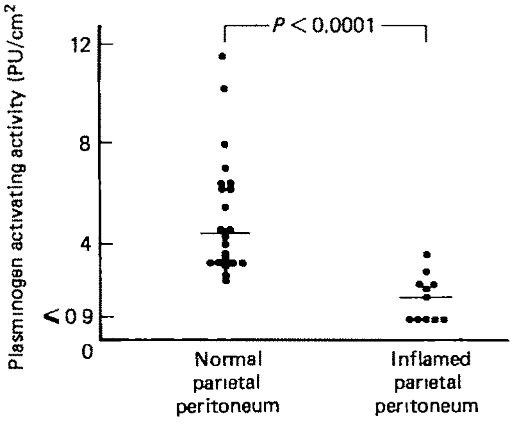

Figure 1 *The plasminogen activating activity of normal and inflamed parietal peritoneum (bars show median values)*

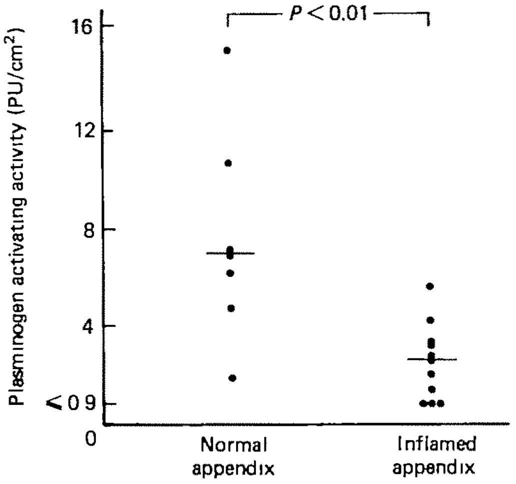

Figure 2 *The plasminogen activating activity of normal and inflamed appendix serosa (bars show median values)*

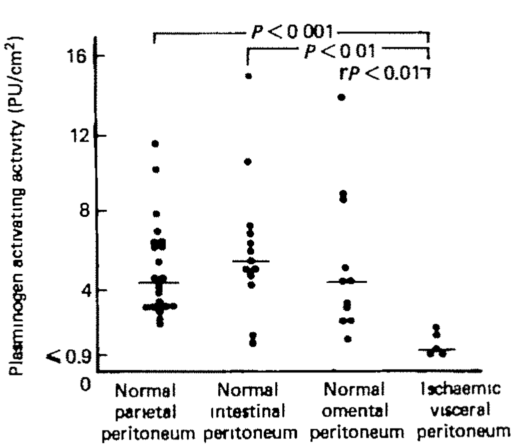

Figure 3 *The plasminogen activating activity of normal parietal, intestinal (including appendix), and omental peritoneum compared with ischaemic visceral peritoneum (bars show median values)*

Plasminogen activator is found in a variety of normal and neoplastic tissues and its main action is to initiate extracellular proteolysis mediated through the plasminogen–plasmin system[13]. Vascular endothelial PAA is important in thrombolysis[14] and, by analogy, it has been considered that peritoneal PAA is important in determining whether fibrinous abdominal adhesions are lysed or organized into permanent fibrous tissue[6–9].

The technique of tissue extraction of plasminogen activator used in this study has been described[15] but not used for the measurement of peritoneal activity. Previous workers have either used the Gelfilm disc (Upjohn, USA) technique[9,16,17,21], or have placed fresh peritoneal biopsies directly on to a fibrin plate[6,8]. The Gelfilm disc technique has the advantage that only mesothelial cells are sampled but it is not possible to be certain that a complete monolayer is obtained or that the remaining peritoneal surface does not contain plasminogen activator. The use of peritoneal biopsies carries the disadvantage that plasminogen activator in submesothelial tissue will also be assayed, although histological studies with the fibrin slide technique suggest that the large majority of plasminogen activator in such biopsies is located in the mesothelium[6–8,18]. We initially tried the Gelfilm disc technique in patients but found very low levels of PAA in discs applied to normal peritoneum.

The present study has demonstrated that normal human peritoneum contains plasminogen activator, that there is little site-to-site variation, and that peritoneal PAA is reduced in inflammation and ischaemia. While previous studies have shown that the normal peritoneal mesothelium of rats, guinea pigs and dogs has PAA[6–9,17,19], and activity has been demonstrated in human small bowel serosa[8] and human mesothelial cell cultures[17]. Only one previous paper reports on a detailed study of human peritoneal PAA. Merlo *et al* showed significant variations in the fibrinolytic activity of normal human peritoneum taken from different sites using the Gelfilm disc technique[21].

The reduction in peritoneal PAA observed after trauma, ischaemia or inflammation seen in this and other studies[6–9] may be related to mesothelial cell injury, mesothelial release of plasminogen activator, or a combination of these mechanisms The time course of such reductions in peritoneal surface PAA may also be important as organization of fibrinous adhesions does not take place experimentally until 5–7 days[6,9]. The timing of these events in man is probably similar, but requires further investigation.

The finding of decreased PAA in patients with peritoneal inflammation and ischaemia, conditions which produce adhesions, supports the unifying hypothesis that a reduction in mesothelial PAA leads to fibrous adhesion formation.

Surgical strategy in primary retroperitoneal tumours

G. Serio, P. Tenchini, F. Nifosi and C. Iacono

Surgical Clinic, Clinica Chirurgica, University of Verona, Verona, Italy
Correspondence to:
Professor G. Serio, Clinica Chirurgica, Università di Verona, 37100 Verona, Italy

Sixty-nine patients with primary retroperitoneal tumours (17 benign, 52 malignant including 4 malignant tumours of uncertain origin) were reviewed to determine the best form of surgical strategy. Total resection was performed in 88 per cent of benign cases and in 65 per cent of malignant cases. In 62 per cent of the total resections for malignant tumours, en bloc *excision included adjacent organs or anatomical structures. Operative mortality rate (in terms of the total number of operations performed) was 5 per cent. Postoperative complications occurred in 14 per cent and recurrences in 35 per cent. The overall 5-year survival rate was 67 per cent in patients with totally resected tumours and zero in patients whose tumours were treated by partial resection or biopsy. An aggressive surgical approach aimed at total excision of the tumour is the best form of therapy currently available. In the totally resected retroperitoneal tumour, the use of adjuvant radiotherapy and/or chemotherapy depends on the grade of the malignancy and clearance as assessed histologically. Careful follow-up based on the use of computerized axial tomography and ultrasound allows early identification of recurrence at a stage when the recurrence is amenable to total resection.*

Keywords: Surgery, primary retroperitoneal tumour

For various reasons surgeons have been unable to agree on any single optimal strategy in the treatment of primary retroperitoneal tumours; 65–86 per cent are malignant[1,2], and, in addition to substantial differences in histology and evolution, they respond differently to adjuvant therapy. Owing to the considerable sizes they may reach, resection of these tumours may be technically difficult, and their relative rarity, with an incidence of 0·07–0·2 per cent of all tumours[2,3], makes it difficult to achieve significant statistical assessment of the different therapeutic tactics available. Moreover, discrepancies in surgical strategy are accentuated in the treatment of recurrences, the incidence of which ranges from 20 to 80 per cent[1,2,4–7].

Patients and methods

Sixty-nine histologically assessed cases were seen in our Institute during the period 1970–78. These comprised primary neoplasms originating in the retroperitoneal cavity excluding lymphomas and primary tumours of retroperitoneal organs (pancreas, kidneys, adrenal glands, urinary excretory tract). There were 35 men and 34 women; the mean age was 48·5 years (range 4–80 years) and the mean duration of symptoms was 6·5 months (range 1–72 months). Palpable masses, with or without pain, were present in 60 cases (87 per cent), gastrointestinal signs in 18 (26 per cent), urinary signs in five (7 per cent), general signs in 18 (26 per cent) and arterial hypertension in three (4 per cent). In two cases the clinical onset of the tumour was acute with a picture of intestinal occlusion and haemoperitoneum. Eleven of the 48 malignant tumours (23 per cent) had already been operated on once or twice elsewhere.

The distribution of the tumours in terms of histological and histogenetic characteristics is summarized in *Table 1*. The maximum tumour diameter of malignant tumours ranged from 13 to 35 cm, benign tumours from 5 to 17 cm. Metastases were observed in 11 of the 47 malignant primary retroperitoneal tumours (23 per cent): 4 out of 31 cases of mesodermal tumour, 6 out of 9 cases of ectodermal tumour, and 1 out of 7 cases of embryonal tumour. The sites affected were the liver (six cases), the skeleton (three cases) and lungs (four cases) and distant lymph nodes (one case).

Up to 1977 the diagnostic techniques available were urography, gastrointestinal contrast radiography and angiography (aortography, selective visceral and parietal arteriography, cavography). Since 1977 all cases have been examined by computerized axial tomography, often in combination with ultrasonography.

Surgical therapy

Fifteen of the 17 benign tumours were treated by total resection and the other two by partial resection and biopsy. Of the 48 malignant tumours and 4 malignant tumours of uncertain origin (paragangliomas), 34 (65 per cent) were subjected to total resection, 14 (27 per cent) to partial resection and 4 (8 per cent) to diagnostic laparotomy. Total resection is defined here as the macroscopic removal of all of the neoplastic mass, regardless of the presence or otherwise of microscopic 'residues' at the resection margins of the tumour or in the tumour cavity.

Local recurrences occurred in 12 (35 per cent) of the 34 malignant primary retroperitoneal tumours subjected to total resection. No recurrences occurred in benign tumours. The total number of reoperations was 18 (six total resections and 12 partial resections or laparotomy, *Table 2*).

Out of 40 total resections (34 first operations and 6 reoperations) for malignant primary retroperitoneal tumours, 25 cases (62 per cent) required *en bloc* excision of adjacent organs or anatomical structures (vessels, skeletal tissue). This also proved necessary in nine (39 per cent) of 23 partial resections. The frequency of the various organs involved in this total of 34 *en bloc* resections is shown in *Table 3*. In the course of 40 total resections for malignant tumour, it was necessary on 17 occasions (42 per cent) to deal with the technical problems relating to involvement of major blood vessels such as the vena cava or aorta or vessels of vital importance (portal triad, superior mesenteric vein). These were solved in various ways: by extended dissection, by *en bloc* resection together with the tumour (vena cava in three cases), or by resection followed by reconstruction (vena cava in one case, superior mesenteric vein in two cases).

Radiotherapy

In our Institute none of the cases was treated preoperatively with radiotherapy. After total resection, adjuvant radiotherapy was given in four cases at doses of 50–70 Gy. Supplementary radiotherapy was given in six cases treated by partial resection, and palliative radiotherapy in three cases of diagnostic laparotomy.

Chemotherapy

Chemotherapy was given preoperatively in only two cases (in one malignant teratoma and in one embryonal carcinoma, both of which had a yolk sac tumour component). After five or six courses of polychemotherapy*, the original tumour masses, measuring 9 and 15 cm respectively, had shrunk to 2.5 and 8 cm maximum diameter, making total resection of the two tumours possible after 5 and 8 months respectively (*Figure 1*). Postoperative chemotherapy was given in three cases after total resection, in five of the cases subjected to partial resection and in three cases after diagnostic laparotomy.

Since 1980 a protocol has been applied to subjects undergoing total resection, which establishes the indication for adjuvant radiotherapy or chemotherapy on the basis of histological typing, tumour grading and the results of a microscopic examination of the suspect areas of the tumour bed (*Table 4*)

Long-term follow-up

In patients undergoing total resection for malignant primary retroperitoneal tumour, the follow-up examination (clinical examination and history, chest X-rays, computerized axial tomography scans and/or ultrasonography, skeletal X-rays or bone scan, monitoring of markers such as urinary vanethylmandelic acid, plasma α-fetoprotein, chorionic β-gonadotrophin, carcinoembryonic antigen) were performed after 3–6 months during the first 2 years and every 6–12 months in subsequent years (*Table 4*)

In patients undergoing partial resection or exploratory laparotomy treated with radiotherapy and/or chemotherapy, follow-up examinations were performed every 3 months in order to evaluate the biological response of the tumour to the treatment and the possibility of further surgery.

Results

Operative mortality

Four patients with malignant primary retroperitoneal tumours (two exploratory laparotomies and two partial resections) died

PRT, primary retroperitoneal tumour; CT, chemotherapy; RT, radiotherapy; *computerized axial tomography and/or ultrasonography, chest X-ray, skeletal X-ray or ^{99m}Tc scan, tumoral markers

within 30 days of the operation. In terms of the total of 87 operations or reoperations for benign or malignant tumours the mortality rate was 5 per cent, while in terms of the 70 operations for malignant tumour it was 6 per cent.

Postoperative complications

Complications occurred in 14 per cent of patients and included haemorrhage, peripheral neurological deficits, gastrointestinal fistulae, persistent lymph leaks and cardiopulmonary insufficiency.

Local recurrences

These occurred in 12 (35 per cent) of the 34 malignant tumours subjected to total resection. No recurrences occurred in benign tumours. Recurrences appeared after periods ranging from a minimum of 7 months to a maximum of 54 months (mean 21 months). In patients operated on before 1980 the mean time to appearance of recurrence was 25 months, while in those operated on after this date and included in the follow-up schedule indicated in *Table 4*, the mean disease-free period was 11·5 months. In the four recurrences making up this group the tumours did not exceed 10 cm in diameter (*Figure 2*), were asymptomatic and were all removed by total resection; those observed before 1980 all exceeded 10 cm in diameter (up to 30 cm), were accompanied by clinical signs of compression or by pain and could be completely resected in only two out of six cases.

Metastases

Seven of the 34 patients (20 per cent) undergoing total resection for malignant tumours presented with distant metastases, either accompanied or not by local recurrence. The sites most affected were the liver (four cases), lung and bones (two cases) and peritoneum (one case).

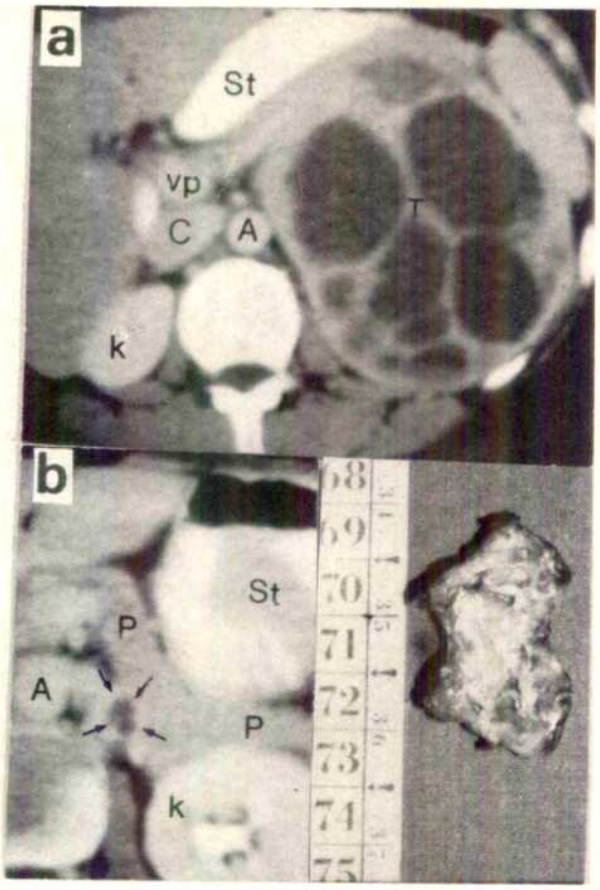

Figure 2 **a** *Computed axial tomography scan of bulky paraganglioma in the left paravertebral gutter.* **b** *Local recurrence of tumour, 2 cm in size (arrows), detected 1 year after the operation. T, tumour; P, pancreas; vp, portal vein; C, cava; A, aorta; St, stomach; k, kidney*

Long-term survival

This was evaluated using the product-limit method[8] in 35 malignant primary retroperitoneal tumours. The result was an estimated overall 5-year survival rate of 46 per cent and a 10-year survival rate of 38 per cent with a median value of 50 months (*Figure 3*). There is evidence of a significant difference (log rank 14920, $P < 0{\cdot}0001$) between the survival curves plotted for tumours undergoing total resection (5-year survival 65 per cent, 10-year survival 56 per cent) and those treated by partial resection or simple diagnostic laparotomy (zero survival at 5 and 10 years). Twelve of the 25 sarcomas (40 per cent) were leiomyosarcoma, the poor prognosis of which is borne out by the zero 5-year survival and a median survival of 15 months.

Discussion

The prospects of curing patients with primary retroperitoneal tumours are currently related, as in the past, to the success of total resection of the tumour. Nevertheless, the involvement of important abdominal organs and vessels, which is observed in a very high percentage of cases at the time the neoplasm is diagnosed, is the main obstacle to the implementation of effective surgery.

The incidence of remote metastases ranges considerably, from 5 to 42 per cent of cases[2,4,9], but would appear to be relatively low in recent surgical studies[1]. In the present review, the percentage of metastases was 23 per cent.

A more aggressive surgical approach, expressed in the form of *en bloc* excision of the neoplasms together with adjacent organs or anatomical structures (kidneys, bowel, pancreas, blood vessels), accounts for the significant increase in total resections in recent reviews rather than this being the result of earlier diagnosis. In the present study, total resection of malignant tumours was performed in 65 per cent of cases, which appears to be satisfactory bearing in mind the fact that 23 per cent of the cases had been partially resected elsewhere. This more aggressive surgical approach is not accompanied by an increase in operative mortality rate, which is now con-

The table shows the number of patients at risk (percentages in parentheses)*

sistently below 10 per cent[1,4,7,10]. It would appear to depend more on the stage of the disease than on the extent of the tissue excision performed[1,7]. In our study the four deaths occurred in subjects with advanced neoplasms; the operative mortality rate in terms of the overall number of operations performed was 5 per cent.

The therapeutic strategy adopted in our Institute for the management of primary retroperitoneal tumour is summarized in the algorithm in *Figure 4*. We should stress that most of the patients suffering from primary retroperitoneal tumour should have surgery, except for a limited number of cases consisting of very debilitated or elderly subjects with metastases, or patients with histologically proved neoplasms whose only prospects of treatment is radiotherapy and/or chemotherapy. In cases where preoperative investigations and surgical exploration provide evidence of a clearly defined mass which can easily be isolated from the adjacent anatomic structures, there is no obstacle to primary total resection of the tumour. In most cases, however, the tumour mass is closely connected (by adhesion or invasion) to one or more organs or important vascular structures and this may require complex *en bloc* excision followed by equally complex reconstruction. In the most recent reviews[1,4,7] this proves necessary in 37–73 per cent of total major excisions, the figure in the present population study being 62 per cent. The risk pertaining to these major resections makes intraoperative histological examination indispensable for the purpose of selecting and excluding from resection those forms in which major excision procedures are not indicated (lymphomas, lymph node metastases, organized haematomas, retroperitoneal fibrosis, giant lymph node hyperplasia) or primary retroperitoneal tumours which are certainly or presumably responsive to radiotherapy and/or chemotherapy (germinal cell tumours, rhabdomyosarcoma, neuroblastoma) which, following suitable treatment, may later prove amenable to surgical treatment (secondary surgery) with a greater chance of success and fewer risks.

The impossibility of performing a total resection should not discourage attempts at partial excision of the tumour, especially in cases where supplementary radiotherapy and/or chemotherapy is planned, as the latter has a better chance of therapeutic success the smaller the tumour mass to be treated[1,4,11].

Recent reviews[1,4,7,10] report overall 5-year survival rates of 30–35 per cent for malignant primary retroperitoneal tumours and retroperitoneal sarcomas. In the latter, survival beyond 5 years does not necessarily depend on eradication of the disease; from a review of cases treated at the Memorial Sloan Kettering Cancer Center in New York, USA[4], it emerges that, while 40 per cent of patients undergoing total resection were still alive at 5 years, only 22 per cent were disease-free.

In the present review, overall 5-year survival of patients with malignant primary retroperitoneal tumours amounted to 46 per cent, while the 10-year survival rate was 38 per cent. The substantial incidence of leiomyosarcomas (28 per cent) adversely affected overall survival.

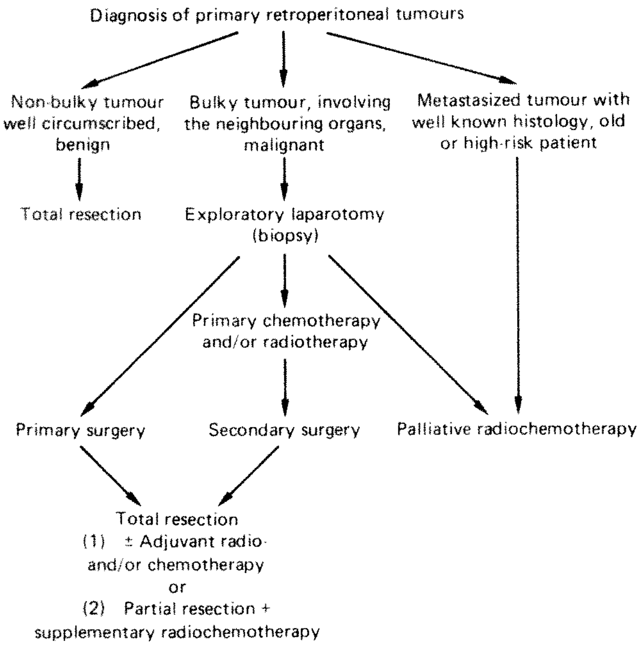
Recent reviews provide evidence that significant 5-year levels amounting to 40–70 per cent of cases can be achieved only in those subjects whose tumours are amenable to total resection. The results of the present survey confirm this finding: 5-year survival was 67 per cent and 10-year survival 56 per cent in the group of totally resected patients.

Closely bound up with the problem of long-term survival is the question of the treatment of recurrences: in recent reviews the incidence after total resection of the tumour ranges from 50 to 77 per cent[1,4,7]. This high incidence is the same even in groups of patients in whom the resection margins of the neoplasms are tumour-free[7].

It was thought that the postoperative use of chemotherapy and/or radiotherapy might modify this state of affairs. In actual fact, however, no statistically convincing evidence has been found[4,7] for the usefulness of adjuvant radiotherapy and/or chemotherapy, in terms of reductions in recurrence rates and lengthening of the disease-free period, despite the claims of certain investigators[1,12,13].

We believe that an improvement in long-term survival may result from a proper follow-up programme capable of exploiting the diagnostic opportunities afforded by computerized axial tomography and/or ultrasonography and, in certain cases, by a number of specific tumour markers, enabling us to detect small-sized recurrences at the preclinical stage.

As the findings of the present study show, surgery at the preclinical stage offers good prospects of a complete cure. Moreover, the prospects of surgical success achievable in these conditions make it possible to avoid the indiscriminate use of radiotherapy and/or chemotherapy after total resection, such therapy being confined to cases of high grade malignancies or to cases with evidence of persistence of microscopic residues in the tumour cavity.



Diagnosis of primary retroperitoneal tumours
Non-bulky tumour well circumscribed, benign
Bulky tumour, involving the neighbouring organs, malignant
Metastasized tumour with well known histology, old or high-risk patient
Total resection
Exploratory laparotomy (biopsy)
Primary chemotherapy and/or radiotherapy
Primary surgery
Secondary surgery
Palliative radiochemotherapy
Total resection
(1) ± Adjuvant radio- and/or chemotherapy
or
(2) Partial resection + supplementary radiochemotherapy

This report details the outcome after clinical diagnosis of mammary fibroadenoma in 110 women aged under 35 years. After fine needle aspiration cytology, and subsequent exclusions and failures of follow-up, 92 lesions were observed for a mean of 47 weeks (range 13–90 weeks), with regular measurements until removal of persisting lesions at 12 months. Fifteen lesions disappeared and 56 had the classical histology of fibroadenoma, mean size 2·5 cm; 30 of the latter continued to grow throughout the study. Cytology is essential to exclude malignancy if conservative treatment is considered, and is helpful in identifying a benign lesion. A period longer than 12 months may be required for resolution of a fibroadenoma and removal under local anaesthesia as a day case offers a simple alternative.

Keywords:

In 1985 we reported a retrospective study of 134 patients in whom a clinical diagnosis of fibroadenoma had been made at our breast clinic[1]. On histological examination eight patients had an unsuspected carcinoma (all but one being over 35 years of age) and 58 had a localized fibrocystic change or other benign cause. Thus only 51 per cent had what histologically was considered to be a true fibroadenoma. Similar findings concerning clinicopathological correlations have recently been reported from Cape Town[2]. Realization that the natural history of fibroadenoma was ill-understood stimulated a prospective study to observe the course of fibroadenomas which were clinically diagnosed in women aged less than 35 years, provided fine needle aspiration cytology excluded unsuspected malignancy.

Patients and methods

Between February 1985 and February 1986 all patients attending our breast clinic with a clinical diagnosis of fibroadenoma and who were under the age of 35 years were asked if they would be prepared to enter the study. The clinical diagnosis was agreed by two clinicians, one a consultant surgeon. There was no limit set on the size of the lesion. If consent was given a fine needle aspiration was performed, and fixed and air-dried smears were prepared as previously reported[3]. Provided that the report indicated a smear of satisfactory quality (if not, permission was sought to repeat it) and did not demonstrate any suspicion of malignant cells, arrangements were made to review the patient at a 1 month and then at 3-monthly intervals at a special clinic. At each visit the size of the lesion was measured with engineer's calipers by one of us (S.W.) and at 12 months all persisting lesions were excised. Indications for excision during the course of the study were (1) rapid increase in size of the breast mass, (2) patient requesting removal or (3) patient moving out of the locality. Change in size during the course of the study was determined by comparing the initial size with that measured during and at the end of the study period. This estimate of change was confirmed by independently examining plots of size against time. Lesions were classified as increasing in size, decreasing in size or remaining static. Those regarded as indeterminate were included in the static group.

Results

During the period of study 110 patients had a clinical diagnosis of fibroadenoma. Fourteen were excluded for the reasons given in *Table 1*, and 11 were lost to follow-up. Of the three suspicious aspirates, cancer was confirmed in one patient aged 25, the second lesion was found to be a reactive lymph node on biopsy and the third woman had a normal second biopsy on a poorly defined lesion. Eighty-five patients completed the protocol; the mean time of follow-up was 47 ± 17 weeks (range 13–90 weeks). Seven patients had two fibroadenomas: the total number of clinical fibroadenomas observed therefore was 92.

Natural history

Fifteen of the 92 (16 per cent) clinical 'fibroadenomas' disappeared during the course of the study; 77 persisted and were excised. Twenty-five lesions were excised within 9 months of the start of the study, ten on account of steady increase in size and 15 for reasons given above. The remaining 52 were excised at the end of the study.

Histology

The histology of the 77 persisting lesions was considered to be that of a true classical fibroadenoma (i.e. an encapsulated lesion of typical epithelial and stromal pattern) in 56 cases. Twenty-one were reported as other lesions, mostly fibroadenomatoid nodules (*Table 2*). These are regarded as a type of fibrocystic change which demonstrates focally the epithelial and stromal features of a fibroadenoma[4]. The incidence of a *clinical* diagnosis of fibroadenoma proving to be a classical fibroadenoma on histology was therefore 73 per cent.

Changes in size

Of the 77 persisting lesions 49 increased in size and 28 remained static (including two which possibly became smaller). Increase in size occurred both in those with a proven true fibroadenoma and in the 'other histology' group (*Table 3*).

Fibrocystic change	
Fibroadenomatoid nodule ($n=12$)	6
Others ($n=6$)	3
Normal breast ($n=3$)	0

Table 4 *Age and contraceptive pill usage related to growth pattern of proven fibroadenoma*

Growth pattern	Mean (range) age of patient (years)	Exposed to current OC usage
Increase in size ($n=40$)	23·2 (17–33)	16 (40%)
Static or indeterminate ($n=16$)	24·8 (18–35)	6 (38%)

OC, oral contraceptive

Histological fibroadenomas. Of 56 proven fibroadenomas, 40 increased in size during the study. The mean size reached was 2·5 cm (range 1·0–4·5 cm). Ten reached their maximum size during the first few months of the study and then remained static. The average size attained was 2·0 cm (range 1·0–3·0 cm). Thirty fibroadenomas continued to grow throughout the period of study reaching a maximum mean size of 2·7 cm (range 1·3–4·5 cm) at the time of excision. Fourteen grew to a size exceeding 2·0 cm and four were over 4·0 cm. The relationship between change in size, the age of the patient and contraceptive pill usage is given in *Table 4*. No differences were noted. Pathological size was recorded in all histologically proved fibroadenomas. The relationship between maximum clinical size and pathological size correlated well.

'Other histology' group. Nine of the 21 other lesions increased in size. Six of the 12 fibroadenomatoid nodules increased in size and six remained static. The other three lesions showing an increase in size were reported as fibrotic nodules (two cases) and sclerosing adenosis (one case).

Fine needle aspiration cytology

Fine needle aspiration was reported to be consistent with a fibroadenoma in 60 of 77 patients whose lesions were excised: this judgement was based on a finding of cohesive sheets of clearly benign epithelial cells together with dispersed bare nuclei representing myoepithelial cells[5]. The relationship with the final histological diagnosis is given in *Table 5*. Eight of the 12 fibroadenomatoid nodules had findings identical to those observed for true fibroadenomas. Fine needle aspiration cytology was consistent with a fibroadenoma in six of the 15 lesions which resolved during the period of study.

Discussion

In our previous study we reported that the relationship between the clinical and pathological diagnosis of a fibroadenoma was not exact. The current prospective study confirms this finding and only 56 of 77 lesions (73 per cent) excised on the clinical belief that the patient had a fibroadenoma were pathologically proved to be such. As true fibroadenomas and the pathological conditions mimicking them are now regarded as aberrations of lobular growth and not neoplasms, these difficulties of discrimination on physical examination from other benign alterations of structure may not seem surprising[6,7]. Since many of these 'others' are fibroadenomatoid lesions the discrimination becomes less important. What is important is the discrimination from cancer.

Table 5 *Fine needle aspiration cytology related to final diagnosis in 77 excised breast lumps believed clinically to be fibroadenomas*

Fine needle aspirate	True fibroadenoma	Fibroadenomatoid lesion	Other benign	Normal
Consistent	50	8	2	0
Not consistent	6	4	4	3

In our previous report we noted that eight out of 134 patients with a clinical diagnosis of fibroadenoma had a carcinoma of the breast; these eight patients were all older than 35 years of age. In the present series three patients under the age of 35 years had positive (one case) or suspicious (two cases) reports for malignancy on fine needle aspiration cytology and were therefore excluded from the study. One of these (aged 25 years) was subsequently proved to have breast cancer. Without the availability of fine needle aspiration cytology fibroadenomas, diagnosed clinically, should not be treated conservatively, at least in women over the age of 25 years. Apart from identifying the cases of cancer, fine needle aspiration cytology is useful in that the typical appearances of a 'fibroadenoma' are further evidence of the benign nature of the mass.

The literature on 'fibroadenomas' suggests that they are self-limiting, growing to a size of 2 cm or so and then remaining static. For this reason some manage them conservatively. Our careful follow-up of fibroadenomas over a period of 12 months suggests that not only do most clinically diagnosed fibroadenomas persist but that over half (49 of 92) continue to grow. Some grow for a period and then become static but others continue to show steady growth and may reach over 4 cm in size. However, in contrast to usual teaching, there was no relationship between the age of the patient or oral contraceptive usage and growth pattern.

Growth apart, it is clear from this study that most clinically diagnosed fibroadenomas persist; only a small percentage (16 per cent) spontaneously resolved and less than half of them had fine needle aspirates consistent with a fibroadenoma. Nevertheless, it must be recognized that more than 12 months may be required to bring about satisfactory resolution to the fibrosed stage similar to that occasionally noted by many pathologists as an incidental feature in breast tissue removed for other reasons.

As a result of this prospective study it is reasonable to suggest that a typical clinical fibroadenoma can be treated conservatively in women under 35 years, but only if an adequate cytological smear obtained by fine needle aspiration does not contain malignant or suspicious cells. Careful follow-up is still necessary over a period of 12 months as these lesions may continue to grow. Many may consider it simpler to remove them as a day case under local anaesthesia.

Surgical significance of non-toxic iodine-avid goitre

M. Kalra and S. K. Khanna

Department of Surgery,

Education and Research,
Chandigarh-160012, India
Correspondence to:
Professor S. K. Khanna

During the period 1970–87, of 1580 patients operated on for non-toxic nodular goitre, 17 satisfied the laboratory criteria for iodine avidity. All of these goitres were non-endemic, with no evidence of enzymatic deficiency. Preoperative thyroxine markedly reduced the surgical morbidity by decreasing the size and vascularity of the gland.

Keywords: Goitre, iodine deficiency

Iodine-avid goitre has been discussed in the literature synonymously with endemic goitre, and extensive iodine metabolism studies have been performed in goitrous and non-goitrous subjects of endemic areas[1–3]. Endemic goitres have been classically described as having a high affinity for iodine, with an inverse correlation between the quantity of iodine excreted in the urine and radioactive iodine uptake by the gland[4,5]. However, adjustment to iodine deficiency is surprisingly good provided the deficiency is not too severe.

In endemic goitres no clearly defined biochemical abnormalities have been detected. There is no large reservoir of unused inorganic iodine in these glands and no block in the genesis of hormones. The proteins of the thyroid appear to be normal and antithyroid antibodies are absent[1,4,5].

Non-toxic iodine-avid goitre may not always be endemic in origin. This variety of iodine-hungry glands is sporadically encountered and is not well described in the literature. Clinical recognition of this condition is, however, important to avoid undue morbidity during surgery. Our own experience with this type of goitre over the past 17 years forms the basis of this report.

Patients and methods

Of 1580 patients with non-toxic multinodular goitre operated on in this hospital between 1970 and 1987, 17 patients satisfied the criteria laid down for iodine avidity (*Table 1*). There were five male patients and 12 female patients, with ages ranging from 14 to 65 years. None of the patients belonged to an area in which goitre is endemic, although two gave a history of goitre in the neighbourhood, and one patient had two cousins suffering from goitre.

Clinical examination revealed a massive goitre in eight patients (*Figure 1*) and the others had a moderately enlarged gland. Massive goitre was arbitrarily defined as one extending from the chin to suprasternal notch, and from the outer border of one sternomastoid to the other. In all but two patients, the gland was multinodular. An audible bruit was present in three patients, pressure effects on the trachea and oesophagus were present in three, and one patient had a large retrosternal extension. None showed any clinical evidence of thyrotoxicosis.

The laboratory results for these 17 patients (*Table 2*) showed low or low normal hormone output, a marked tendency to retain iodine, and evidence of markedly increased vascularity on thyroid scan. In the other 1563 patients with non-toxic nodular goitre, the hormone levels and ^{131}I uptake were within the normal range, and the scan showed a patchy uptake. The perchlorate discharge test (performed on five patients) was negative, with ^{131}I discharge 2 h after perchlorate administration ranging from 1 to 5 per cent. Urinary monoiodotyrosine and di-iodotyrosine estimations, to rule out dehalogenase deficiency, were not performed.

Results

Retrospectively, the management could be divided into two phases (*Table 3*).

Phase A (1970–77)

Between 1970 and 1977 iodine-avid goitre was not clinically recognized and both the patients seen in this time period were given Lugol's iodine solution orally for 7–10 days to decrease the vascularity of the gland, as is done in mild thyrotoxicosis. Thereafter, the patients underwent a partial thyroidectomy.

Preoperative iodine led to a marked increase in size of the gland with precipitation of tracheal pressure symptoms in one patient, but the second patient was totally unaffected. At surgery the gland was friable, difficult to handle and extremely vascular, with large surface veins carrying oxygenated blood, an appearance similar to arteriovenous fistula. Surgery lasted for 5–6 h; 6–9 units of blood were transfused and both patients required tracheostomy at the end of the operation. One of the patients had intraoperative hypotension, transient thrombocytopenia (possibly due to massive blood transfusion) and temporary postoperative vocal cord palsy and hypoparathyroidism. Histology of the gland (*Figure 2*) showed evidence of increased vascularity, the follicles containing scanty colloid with hyperplasia of the epithelial lining along with infolding and papillary projections. There was no significant lymphocytic

infiltration. In the absence of the clinical details, this picture could be easily mistaken for thyrotoxicosis.

Phase B (1978–87)

The clinical entity had been recognized by 1978 and all the patients were given l-thyroxine (0·2–0·3 mg/day) for a minimum period of 6 months before undergoing partial thyroidectomy. There were 15 patients in this group, nine of whom have been operated on so far; four patients are awaiting surgery and two have been lost to follow-up.

Pretreatment with l-thyroxine for 6 months resulted in a marked decrease in the size of the gland (*Figures 3* and *4*) in 12 of 13 patients, with complete relief from pressure symptoms in the remaining two patients. Partial thyroidectomy was technically simple, the gland being firm and easy to excise. Mean duration of surgery was 3·2 h and 0–2 units of blood were required. No significant problems were encountered during or after surgery. Histology (*Figure 5*) revealed a quiescent gland, the follicles being densely packed with colloid and lined by flattened epithelium.

All patients operated on in both groups were given l-thyroxine postoperatively, 0·2 mg daily for 2 years. Follow-up ranged from 2 to 5 years. Goitre reappeared in the pyramidal

lobe in one patient, presumably because it was not excised at the initial surgery. In the other patients, including those who have been followed up after cessation of l-thyroxine at the arbitrarily fixed limit of 2 years, no recurrence has been noticed so far. Whether or not a longer period of thyroxine medication is necessary in such patients is not known. Clinically these patients remained euthyroid even after the cessation of thyroxine.

Discussion

There is no single cause of iodine deficiency goitre; it is due to the interplay of many factors, such as the severity of iodine deficiency, the rates of iodine loss from the body, the relative efficiency of the iodine-trapping mechanism of the gland and its biosynthetic activity[1]. However, some authors have tried to suggest that the cause of endemic goitre is faulty iodine utilization owing to impaired organic binding, superimposed on severe iodine deficiency[6]. They have performed perchlorate discharge tests after pretreatment with 2·0 mg potassium iodide and found abnormal discharges in goitrous patients and no discharge in non-goitrous inhabitants of an endemic area. These findings may explain why only part of the population of an endemic area develops goitre, whereas the others adapt successfully to iodine deficiency without the enlargement of their glands. It remains to be proved whether this abnormality is the primary cause of goitre or is a secondary effect. Response of these goitres to iodine administration has also been studied[7], but reported experience of any problems during surgical management is lacking.

However, none of the patients seen in this group with the classical biochemical characteristics of iodine hunger came from an iodine deficiency goitre zone. Therefore, sporadically occurring iodine-avid goitre should be considered a distinct but rare entity. Its aetiology is not clear. It is not congenital because it occurred over a wide age range and the perchlorate discharge test was negative. Dehalogenase deficiency could not be tested for, owing to the lack of laboratory facilities but its involvement cannot be ruled out. Clinically, iodine-avid goitre does not have any distinct parameters to differentiate it from other non-toxic nodular goitres. In this study 47 per cent were massive, 88 per cent were nodular and 18 per cent had a bruit and/or pressure effects. Therefore the diagnosis is based purely on the laboratory criteria laid down.

When surgery was performed without preoperative L-thyroxine the gland was found to be extremely vascular and friable, and bled profusely at the slightest touch. The surgery was therefore prolonged and a large volume of intraoperative blood replacement was necessary. Preoperative thyroxine for an arbitrarily decided period of 6 months decreased the size and vascularity of these goitres, relieved pressure symptoms and greatly diminished the surgical morbidity. The surgical significance of this condition is that it should be recognized before operation and appropriate preparation with thyroxine undertaken if major operative difficulty is to be avoided.

Splenectomy for massive splenomegaly

J. H. F. Shaw and M. Clark

University Department of Surgery, Auckland Hospital, Auckland, New Zealand

Correspondence to:
Mr J. H. F. Shaw

Twenty-four patients who underwent resection of giant spleen (spleen weight >1·5 kg) have been reviewed to determine the difficulties and benefits of the procedure and, in particular, whether the use of adrenaline injection into the splenic artery could safely reduce technical difficulty. Although morbidity was higher in patients with giant spleens compared with those undergoing resection of smaller spleens the incidence of serious complications was small, and there were no operative or in-hospital deaths. In addition, virtually all patients benefited either on the basis of minimized haematological defect, or palliation of symptoms. Further, the injection of 1 ml of 1:10 000 adrenaline into the splenic artery before splenic mobilization reduced the splenic volume by approximately 40 per cent on average, and resulted in improved exposure, thereby facilitating the procedure.

Keywords: Elective splenectomy, haematological disorders, Hodgkin's lymphoma, overwhelming infections, thrombocytopenia, giant spleen, adrenaline

Elective splenectomy is a frequently used technique in the diagnosis and therapy of a variety of haematological disorders, including the treatment and staging of some patients with lymphoma[1,2], the treatment of hairy cell leukaemia[3] and for diagnosis of inexplicable splenomegaly[4]. However, most reports on the usefulness of splenectomy in the diagnosis and management of haematology patients focus on patients with normal sized, or moderately enlarged spleens, and there has been a widely held belief that resection of giant spleen is associated with major hazards, and that it is ineffective in providing palliation of symptoms and/or correction of haematological[6] abnormalities.

Goldstone[6] reported that splenectomy for massive spleen provided symptomatic relief in some patients, but that this gain was balanced by a high operative mortality rate. In contrast, Wobbes *et al.*[7] and Bickerstaff and Morris[8] have reported that resection of giant spleen can be accomplished with minimal risk of mortality, and that satisfactory palliation and/or correction of haematological abnormalities can be achieved.

Over recent years, most elective splenic surgery in Auckland has been performed by one of two surgeons in one centre. We have reviewed the local experience of splenectomy for massive splenomegaly and, in particular, we have asked: can resection of giant spleen be undertaken safely; is the procedure effective in providing palliation and/or minimizing the haematological defects; is injection of adrenaline into the splenic artery before mobilization of the spleen useful for both patient and surgeon?

Patients and methods

From a total of 148 patients who underwent elective splenectomy at Auckland Hospital (1978–88), 24 had giant spleens (weight >1·5 kg). There were 14 men and 10 women (mean age 60 years). The indications for splenectomy are summarized in *Table 1*.

Seventeen operations were done through abdominal incisions and in seven a thoracoabdominal incision was used. Seven severely thrombocytopenic patients (bleeding times >15 min) received platelet transfusions intraoperatively, and five also required whole blood.

Most commonly the splenic vessels were controlled via the lesser sac before mobilization of the spleen. In the seven patients most recently operated on, 1 ml of 1:10000 adrenaline was injected into the splenic artery after the vessel had been controlled. After the injection, the artery was immediately ligated to maximize the effect of the adrenaline on the spleen while minimizing the systemic effect. The intention was to reduce the volume of the spleen and improve access and ease of dissection, while having only a minor haemodynamic effect (due to the leak of adrenaline into the systemic circulation as part of the contraction of the spleen). After splenic artery ligation the lienorenal ligament was incised, adhesions between spleen and adjacent structures were ligated and divided, and the spleen was mobilized. Finally, the splenic artery and vein were separately ligated.

Pneumococcal vaccine was used routinely (most commonly preoperatively) to minimize the risk of overwhelming postsplenectomy infection. In addition, in order to reduce the risk of wound infection, pneumonia and/or intra-abdominal abscess formation, a single dose of broad spectrum antibiotic was administered on induction of anaesthesia.

Results

The weight distribution of the resected spleens was 1539–3600 g (mean 2142 g), and the final diagnoses are shown in *Table 2*.

The nine patients with cytopenia as the primary indication for splenectomy all had reversal of this problem. Six are alive at an average of 5 months after surgery. Two died at 23 and 36 months after surgery, and the remaining patient was lost to follow-up.

Six splenectomies were performed for diagnosis and a diagnosis was obtained in all. Two had congestive splenomegaly (both alive at 36 months) and the remaining patients proved to have either non-Hodgkin's lymphoma, or myelofibrosis.

The four patients who had palliative splenectomy gained symptomatic relief. One is alive 1 month postoperatively, two died of their malignancy on average 4 years after surgery and another succumbed to overwhelming postsplenectomy infection (pneumococcal meningitis) after 5 months. Five other patients who underwent splenectomy primarily for reasons other than relief of pain also experienced relief from intra-abdominal mass symptoms.

The splenectomies undertaken as initial treatment of hairy cell leukaemia were all successful, either as sole treatment of the leukaemia, or as an adjunct to interferon, and all were alive at the time of the study. The patient who had resection of ruptured giant spleen (secondary to chronic myeloid leukaemia) is alive and well at 1 year, and the patient who underwent splenectomy (and splenorenal shunt) for Wilson's disease is also alive after 1 year.

The alterations in splenic volume, blood pressure and pulse rate following the injection of adrenaline are summarized in *Table 3*.

There were no in-hospital deaths and complications are summarized in *Table 4*.

Discussion

The major goals of our study were to assess whether resection of giant spleen is a safe procedure with an acceptable complication rate, to determine whether the procedure was an effective means of palliating symptoms and/or reversing haematological abnormalities, and to assess whether the intra-arterial injection of adrenaline into the splenic artery could safely reduce the technical difficulty of the operation. With respect to the first two goals, both premises are true, and our study confirms the findings of Bickerstaff and Morris[8].

Good results for surgical treatment of giant splenomegaly are dependent on a team approach involving surgeon, haematologist, and anaesthetist, coupled with meticulous surgical technique. In their account of the subject, Bickerstaff and Morris[8] recommend not using adrenaline to reduce the size of the spleen, but the paper on which they base this was written in 1951. Our experience with this technique is different and, in the seven cases where it was used, the most important finding was the ease with which the operation could be performed. The 40 per cent reduction in splenic size results in the creation of a space around the spleen that improves exposure, in particular the exposure of the diaphragmatic adhesions that can present a technical challenge. The procedure was not associated with any complications aside from minor changes in blood pressure and heart rate which were not of any clinical consequence. It is impossible to estimate whether the use of adrenaline reduced the need for blood replacement, as only five of the 24 patients received intraoperative blood transfusion. However, the 40 per cent reduction in splenic volume that occurred after the adrenaline injection would have resulted in a significant autotransfusion and this is likely to have had a beneficial effect. One potential disadvantage of the procedure is that it would be inappropriate in the presence of an anaesthetic that was particularly sensitive to catecholamine injection but, in most instances, this potential problem could probably be avoided.

We have previously shown that the degree of catabolism in patients with haematological malignancy is associated with bulk of disease, with the most marked degree of catabolism occurring in patients with leukaemia and giant splenomegaly[5]. As splenectomy drastically reduces the bulk of disease in these patients it is probable that the resulting reduction in catabolism is also a factor contributing to the feeling of well-being experienced by most of these patients after surgery.

As with the other reported studies, we have shown that resection of a giant spleen is associated with a higher rate of complications than the resection of smaller spleens. Goldstone[6] points out that patients undergoing resection of a giant spleen are not only older than most other patients undergoing splenectomy, but the underlying diseases are more likely to render the patient prone to infection and/or haemorrhage. Most patients in our study had haematological malignancies known to be associated with bleeding disorders, immune defects, and catabolic metabolism[1–5]. However, despite this, there were no in-hospital deaths in our series, and of the six patients who died during the period of our study, only one did so within 1 year of operation while 21 out of 24 patients experienced either palliation of symptoms or minimization of their haematological problem.

We conclude that splenectomy plays an important part in the diagnosis of unexplained giant splenomegaly. Resection of giant spleen effectively minimizes both pressure symptoms and haematological problems, and survival is long enough to make this worthwhile. Although morbidity is comparatively high in patients undergoing resection of giant spleen most complications are minor and transient. The injection of 1 ml of adrenaline (1:10000) effects: a 40 per cent reduction of splenic volume, an autotransfusion for the patient, and greatly facilitates the ease of dissection for the surgeon.

Acknowledgements

The authors acknowledge Kabi Vitrum Laboratories, Stockholm, Sweden, for financial support to undertake this study. They also acknowledge the other clinicians involved in the management of the patients presented here, in particular Drs John Mathews, Rae Varcoe, John Buchanan and Steve Palmer and Mr Ronald Kay. Finally we are grateful to Mr Harry Erlam for assistance with manuscript preparation.

Right splenorenal bypass: a technical suggestion

G. Battisti, F. Stio and M. Marigliani

VI° Department of Surgery, University of Rome, Italy
Correspondence to: Dr G. Battisti

At present the most effective treatment of early renal artery stenosis is aortorenal bypass using a prosthesis or autogenous vein graft. However, this may prove impossible in patients with marked aortic arteriosclerosis and in those who have had previous surgery to the abdominal aorta. Many procedures have been suggested to solve these problems without using the abdominal aorta. They include transplantation of kidney, hepatorenal arterial bypass, gastroduodenal arterial bypass, iliorenal arterial bypass, the mesenteric–renal arterial bypass, and left splenorenal arterial bypass. It appears that use of the splenic artery for revascularization of the right renal artery has not been described in this context.

The technique involves exposure of the right renal artery after mobilization of the right side of the colon and a Kocher manoeuvre to mobilize the duodenum and head of pancreas. The splenic artery is then isolated as it runs along the upper border of the pancreas to the splenic hilum. This is achieved by opening the gastrocolic ligament, paying attention to preserving the integrity of left gastroepiploic artery. The splenic artery is encircled by a loop and dissected free until the root of the coeliac axis is reached. Bleeding from its small pancreatic branches is controlled by metal clips. The artery is then easily passed through the foramen of Winslow after full mobilization to reach the right renal artery.

After local heparinization, an end-to-side anastomosis between the mobilized splenic and the right renal arteries is made with an interrupted suture of 6-0 Prolene® (Ethicon Ltd., Edinburgh, UK, *Figure 1*). At the completion of the operation in a 67-year-old man in whom we have used this technique the spleen appeared well vascularized and we did not feel that removal was indicated. Clearly, preservation of the left gastroepiploic arcade and short gastric vessels is important in this context. The patient remains well 20 months after surgery.

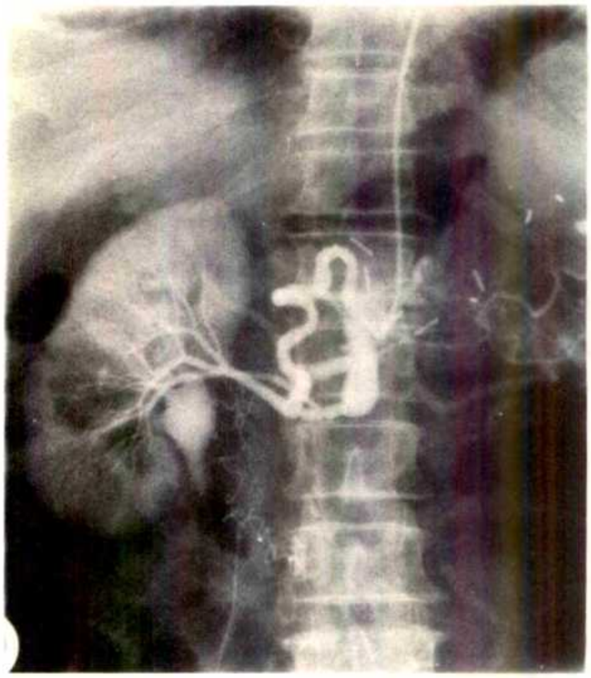

Figure 1 *Selective angiography of the splenic artery made on the seventh day after surgery showing a functioning splenorenal bypass*

We conclude that anastomosis of the splenic artery to the right renal artery may be a further useful method of bypass in renal artery stenosis where direct use of the aorta is contraindicated. Before using the splenic artery one must study its anatomy, length and calibre and ensure that it has no arteriosclerotic areas that might obviate its use.

Surgery in patients with von Willebrand's disease

M. Blombäck, G. Johansson, H. Johnsson, J. Swedenborg and E. Wabö

Departments of Clinical Chemistry and Blood Coagulation, Medicine and Surgery, Karolinska Hospital, S-104 01 Stockholm, Sweden

Correspondence to:
Dr G. Johansson, Department of Surgery, Karolinska Hospital,
S-104 01 Stockholm, Sweden

The risk of bleeding complications in the surgical treatment of patients with von Willebrand's disease has been evaluated. Sixty-four major surgical procedures were performed in 51 patients with various forms of von Willebrand's disease. In 18 cases, the bleeding disorder was unknown at the time of surgery, resulting in bleeding complications in 12 cases (67 per cent). Forty-five operations were carried out in patients in whom the diagnosis of von Willebrand's disease was known at the time of surgery. In these patients, the following haemostatic preparations were given: factor concentrate, fresh plasma, tranexamic acid and desmopressin. Haemostatic complications occurred in three of these operations (6·7 per cent); all were managed easily. No mortality was observed. It is concluded that patients with von Willebrand's disease do not carry an increased operative risk if appropriate precautions are taken.

Keywords: Surgery, von Willebrand's disease, bleeding complications, desmopressin

Von Willebrand's disease includes a number of closely related inherited bleeding disorders[1-4]. The disease is characterized by a tendency to increased bleeding, particularly from surgical incisions and lesions of mucous membranes. This predisposition to bleeding is increased after the intake of platelet inhibitory drugs, such as aspirin. The most severe clinical manifestations include spontaneous haemarthroses and muscular haematomas. In mild cases there may be no clinical symptoms[2,4].

The biochemical defect in von Willebrand's disease is a lack of functional von Willebrand factor, a glycoprotein necessary for the adherence of platelets to exposed subendothelium. This glycoprotein is synthesized in endothelial cells and megakaryocytes, and serves as a carrier protein for factor VIII, the missing factor in haemophilia A. Thus, it promotes both the formation of a platelet haemostatic plug and the coagulation of blood at the site of an injury[4].

A bleeding disorder adds a potential risk to a surgical procedure, although modern substitution therapy should minimize this problem. To obtain further information on morbidity and mortality after major surgery in patients with von Willebrand's disease the outcome of the series of such operations has been analysed.

Patients and methods

There are about 800 patients with von Willebrand's disease who are registered at the Department of Medicine, Karolinska Hospital. In the period 1970–85, 51 underwent major surgery, that is surgical procedures with a hospital stay exceeding 24 h. The surgical procedures ranged from stripping varicose veins to laparotomies, thoracotomies and arthroplasties. The bleeding disorder was classified as severe, moderate or mild, depending on the functional activity of von Willebrand factor in plasma[5]. However, in patients who had operations before 1978, the antigen concentration of the von Willebrand factor was used for the classification[6]. The limits for the three forms were arbitrarily set at less than 5, 5–20 and 21–60 per cent, respectively. All patients with the severe and moderate forms of the disease had prolonged bleeding times. If the bleeding disorder was known of before surgery, prophylactic therapy was given. Treatment was adjusted according to the intended surgical procedure and the seriousness of the von Willebrand's disease, and included the administration of factor concentrate, fresh plasma, desmopressin acetate and tranexamic acid. The contraindication of platelet inhibitors was stressed. The year of operation had an influence on the haemostatic therapy. Thus, during the latter years of the study, more patients were treated with desmopressin acetate than with plasma products.

Appropriate information was collected from the records at hospitals or clinics where the operations were performed. In total, 37 clinics at 20 different hospitals in Sweden, mostly in the Stockholm area, were involved. All records were re-evaluated with respect to classification, haemostatic treatment and bleeding complications.

Results

Disease unknown at operation

Sixteen patients (5 men, 11 women) underwent 18 surgical procedures without the knowledge of the presence of the bleeding disorder. One patient had neglected to give an adequate history of his disease. In the other cases, the diagnosis had not yet been made. The mean age of the patients was 32 years (range 16–46 years). *Table 1* summarizes the results. No mortality was observed. Bleeding complications were observed in 12 patients (67 per cent of surgical procedures): in eight patients there was abnormal oozing either during the operation or in the immediate postoperative period; in four patients large haematomas occurred a few days after operation. Two patients had a reoperation for postoperative bleeding. The haemostatic problem usually required the administration of fresh whole blood, or fresh plasma; in all but one case, further investigation of the coagulopathy was initiated. In the latter case, as in all the other patients without bleeding complications while in hospital, the diagnosis of von Willebrand's disease was made later.

Disease known at operation

Thirty-five patients (13 men, 22 women) were operated on with the diagnosis of von Willebrand's disease having been made preoperatively. *Table 2* summarizes the essential information of these operations. Forty-five various major operations were performed. The mean age of the patients was 35 years (range

5–65 years). There was no operative mortality, and no patient required reoperation for bleeding. In three patients, haemostatic problems were observed, giving an incidence of complications for treated patients of 6·7 per cent.

Discussion

The prevalence of the severe form of von Willebrand's disease is less than 0·001 per cent of the Swedish population. Most patients having this form are known, and have been diagnosed after family screening, or after an episode of abnormal bleeding. In contrast, the heterozygotes with mild forms constitute a significant part of the population. As many of them have not been diagnosed the true prevalence is difficult to establish. Furthermore, even with appropriate analytical methods, conclusive diagnostic evidence is difficult to obtain in some of these cases[7]. The disease is inherited in an autosomal manner, either dominant or recessive[2-4]. Knowledge of its clinical penetrance, together with population and genetic statistics, suggests a prevalence in Sweden of approximately 1 per cent.

In undiagnosed cases of von Willebrand's disease, a careful preoperative history, even in mild forms, often indicates a coagulation disorder, which initiates further evaluation of the haemostatic function. However, there are always patients in whom the diagnosis of von Willebrand's disease has not been made before surgery. In 1973, Silwer reported that surgical procedures in such cases often resulted in severe bleeding complications, sometimes fatal[8]. In the present report the number of complications was approximately the same. However, the clinical outcome of the complications in our study was benign, probably due to improved therapy. Accordingly, abnormal bleeding initiates the transfusion of fresh plasma. Concomitantly, appropriate tests for evaluation of a possible coagulopathy are performed.

Preoperative diagnosis of the bleeding disorder is mandatory in order to prevent bleeding complications. This report demonstrates that the number of bleeding complications in patients in whom von Willebrand's disease was known before surgery was about the same as in patients with normal haemostasis[9]. In fact, none of these bleeding episodes prompted reoperative surgery. This corroborates previous findings by Larsson[10].

The Stockholm area has a population of 1·5 million, and about 100 000 major operations are performed every year (6·7 per cent). The corresponding incidence in patients with von Willebrand's disease registered at this hospital was about the same, i.e. 8 per cent. It has been suggested that the bleeding from mucosal membranes in patients with von Willebrand's disease would result in a significant increase in the number of surgical procedures, especially in the stomach and duodenum[11]. The present study does not support this hypothesis. In fact, very few of the operations were performed because of complications from the bleeding disorder *per se*; there was no difference in the type of surgical procedure performed compared with the corresponding figure in the average population.

In patients with von Willebrand's disease, efficient substitution therapy is easily achieved with factor concentrate. On account of the risks with plasma concentrate, desmopressin is an attractive alternative. It is a synthetic analogue of vasopressin which increases the plasma concentration of the factor VIII—von Willebrand factor complex—thus normalizing the haemostatic defect[12-14]. The experiences reported in surgical patients have been encouraging[15-20]. Because of its recent introduction, only a small number of surgical procedures were carried out after treatment with desmopressin. All these operations were completed without bleeding complications, as has been the case in other recent reports[15-20], a fact which favours the continued use of this drug in patients with von Willebrand's disease.

Surgical risk is similar to normal in patients with von Willebrand's disease. The preferred prophylaxis includes tranexamic acid. In patients with mild forms of von Willebrand's disease desmopressin is preferable to plasma products. In the severe form, the megakaryocytes and endothelial cells are not capable of synthesizing von Willebrand factor[13] and consequently, in such patients, and in subjects synthesizing abnormal molecular forms of von Willebrand factor, desmopressin is not appropriate for prophylactic therapy and should be replaced by plasma products[21]. Furthermore, in those patients, immediate access to an experienced coagulation laboratory is essential especially when extensive surgical procedures are scheduled.

Use of deep tension sutures and buttress plates for frequent relaparotomy

M. R. J. Lansdown and M. J. McMahon

University Department of Surgery, The General Infirmary at Leeds, Great George Street, Leeds LS1 3EX, UK
Correspondence to: Mr M. R. J. Lansdown

After laparotomy and débridement of complex intra-abdominal abscesses, the use of gauze packs and frequent relaparotomy has been suggested as an alternative to tube drainage. An abdominal 'zip fastener' or polypropylene mesh has been used to facilitate relaparotomy, but when sepsis has subsided the wound is ultimately left open and allowed to granulate. As a consequence, myocutaneous flaps or skin grafts are sometimes necessary to obtain skin cover and a cosmetically acceptable result. In our experience, a wound closure system that utilizes buttress plates and plastic-coated wire sutures (Ventrofil®, B. Braun Ltd., Aylesbury, UK) greatly facilitates relaparotomy and can lead to an acceptable final wound that does not require surgical reconstruction.

For upper abdominal abscesses a transverse or 'roof-top' incision is our preferred incision when relaparotomy is likely because the tendency to gape is less than with a vertical incision. Necrotic tissue and pus are removed. Areas destined for reinspection at further laparotomy are lined with non-adherent gauze. The incision is then closed, or partially closed if there is tension when approximating the wound edges, using the Ventrofil buttressed closure system. Up to four pairs of buttresses may be required for a wide 'roof-top' incision. The polypropylene-coated braided wire sutures are placed as a horizontal mattress through all layers of the abdominal wall except the peritoneum, about 3 cm from the edges of the wound (*Figure 1*). Using traction on the sutures the wound is closed to the appropriate degree. Care is taken to ensure that viscera are not trapped between the sutures. It is important that the ends of the sutures are left long after the knots have been tied (*Figure 2*). The design of the buttress plate allows adjustment of suture tension postoperatively without the need to retie the knots, by moving the suture to a different notch in the buttress. The wound can be covered with a loose absorbent dressing or left open to the air.

At relaparotomy the plates are removed and the abdomen is prepared. The knots are easily untied because of the plastic coating, and the free ends of the sutures, which were left long, are secured with artery forceps while relaparotomy is carried out. We have found that there is ample room between the sutures to carry out full inspection, further débridement and repacking. During the procedure, the plates are soaked in aqueous povidone-iodine solution, and the wound is then closed as before. The procedure is repeated until further laparotomy is not needed, and then the buttressed closure is left *in situ* for 4 weeks to allow healing of the fascial layers and to prevent incisional herniation.

This method of wound closure is convenient to use and allows frequent relaparotomy without the need to place new sutures each time.

As abnormal eicosanoid (prostaglandin) metabolism has been suggested as a factor in the aetiology of vasospastic diseases we have measured levels of stable eicosanoid metabolites using a radioimmunoassay in 30 normal subjects and 31 patients with Raynaud's phenomenon. There were 13 patients with primary Raynaud's, ten with Raynaud's secondary to scleroderma and eight men with vibration white finger (VWF) disease. We have also measured platelet aggregation to adenosine diphosphate (ADP), collagen and adrenaline in 19 normal subjects, 22 patients with primary Raynaud's, 12 with Raynaud's secondary to scleroderma and 14 men with VWF. When compared with our normal subjects, patients with VWF have an elevated thromboxane B_2 level, with a normal 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$) level. Their platelets are less sensitive to ADP and collagen. Patients with primary and secondary Raynaud's have elevated thromboxane B_2 levels but this is much more marked in the secondary group. Patients with primary Raynaud's have a normal 6-keto-$PGF_{1\alpha}$ level but in patients with secondary Raynaud's the 6-keto-$PGF_{1\alpha}$ level is markedly raised. The platelets from both groups are more sensitive to ADP and collagen and this is more marked in the secondary group. Whether these phenomena are a cause or an effect of vasospasm remains unknown.

Keywords: Raynaud's, eicosanoid levels, prostacyclin, platelet aggregation

Despite many theories[1] the pathophysiology of Raynaud's phenomenon remains unknown. Recent interest has centred on the possible role of eicosanoids (prostaglandins)[2]. Prostacyclin[3] is a vasodilator that inhibits platelet aggregation; thromboxane A_2 is a vasoconstrictor that induces platelet aggregation. These eicosanoids represent opposite poles of a homeostatic mechanism, an alteration of the balance in favour of thromboxane could produce vasoconstriction and alter platelet behaviour.

Controversy exists regarding what is a 'normal' plasma prostanoid level and this is paralleled by the findings in specific disease states. Several workers have found elevated prostacyclin and thromboxane stable metabolite levels in patients with Raynaud's phenomenon when compared with controls, both in plasma[4–6] and in urine[7].

If normal metabolite levels represent a real difference in circulating parent prostaglandin levels then altered platelet behaviour might be expected. There have been few studies and again there is a lack of consensus. Most work has compared platelet aggregation using the techniques of Born[8] and found that the platelets from patients with Raynaud's phenomenon are more sensitive than those from controls[7,9]. There have been no satisfactory studies of patients with vibration white finger (VWF) disease.

The aim of this study was to clarify the situation regarding eicosanoid levels and platelet behaviour. We have measured plasma thromboxane B_2 and 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$) levels in a series of controls and patients with Raynaud's phenomenon. We have also compared the ratio between the two metabolites with patient diagnosis and *in vitro* platelet behaviour.

Patients and methods

Patients

Eicosanoid levels were measured in 61 subjects, and platelet aggregation studies carried out in 67 subjects. The two parts of the study were carried out at different times; although many subjects participated in both studies, the results for individuals cannot be directly compared.

Subjects suffering from Raynaud's phenomenon have been divided into groups on the basis of a clinical, haematological and immunological assessment. The age and sex distribution of the groups are given in *Table 1*. Six of the normal females in whom we measured eicosanoid levels were menstruating. Their results have been analysed separately because of the known small, cyclical changes in physiological temperature regulation[10]. In the secondary Raynaud's group, one patient has a vasculitis of uncertain aetiology, all the others have scleroderma. The men with industrial VWF disease have all had the disease for at least 2 years and were graded between one and four on the Taylor–Pelmear[11] scale. Most were graded three or four and either were grinders, swagers or operated pneumatic hand-held road breakers.

Eicosanoid measurements

Blood samples were taken at 08.00 hours, after 30 min quiet bed rest, and added to ethylenediaminetetra-acetic acid (EDTA) 1·5 mg/ml of whole blood and 0·9 ml of 40 per cent aspirin solution. The samples were immediately centrifuged at 1000*g* for 20 min, platelet free plasma was frozen at −25°C for later batch assay.

After solid phase extraction using an octa-diocyl-silene column, the eicosanoid fraction was eluted into methyl formate, evaporated and then purified using high performance liquid chromatography. The metabolites were collected and concentrated by freeze drying. Thromboxane B_2 and 6-keto-$PGF_{1\alpha}$ levels were measured using a radioimmunoassay technique.

Platelet aggregation measurements

Venous blood was added to citrate, centrifuged at 200*g* for 10 min, and platelet rich plasma was removed. The residue was respun at 1000*g* for 20 min to yield platelet poor plasma. By diluting the platelet rich plasma with platelet poor plasma, plasma with a platelet count of 250×10^9/litre was obtained which was used for all aggregation studies. They were carried out using a Chrono-log dual channel aggregometer (Chrono-log Corporation, Havertown, USA) and three aggregating agents; two concentrations of collagen, 2 and 4 mg/l; six serial dilutions of ADP: 10, 5, 2·5, 1·25, 0·625 and 0·3125 μM; and finally a single concentration of adrenaline, 5 μM.

Following the addition of an aggregant platelets undergo a shape change and then aggregate into large clumps rendering the plasma increasingly transparent. A platelet aggregation curve is a recording of

light transmission against time; steep curves with large heights represent a greater platelet sensitivity to the aggregant.

For each ADP curve, the angle, the height after 3 min and the maximum height has been recorded. The highest dose of ADP at which aggregation failed to occur has also been noted. For each collagen curve we have measured the duration of the delay before aggregation in seconds (lag phase), the angle, the height after 3 min and the maximum height. For adrenaline we have measured the height of the curves at 3 and 5 min.

All results are expressed as medians with 5 and 95 percentiles. Statistical analysis is by the Mann–Whitney *U* test, results are considered highly significant when $P < 0{\cdot}001$ and significant when $P < 0{\cdot}05$.

Results

Eicosanoid metabolite levels

The plasma thromboxane B_2 and 6-keto-PGF$_{1\alpha}$ levels for each of the diagnostic categories is given in *Figure 1*.

With regard to 6-keto-PGF$_{1\alpha}$, the median result in our normal population was 0·68 ng/ml. There was no correlation between the levels obtained and age, sex or smoking habits. The median level found in patients with secondary Raynaud's was 29 ng/ml. This was highly significantly elevated when compared with each of the other diagnostic groups. Within the secondary Raynaud's group the level did not vary with the duration or activity of the disease. There were no significant differences between the levels obtained in any of the other groups.

With regard to thromboxane B_2, the median result in our normal population was 5·8 ng/ml. Again the levels bore no relationship to age, sex or smoking habits. The median level found in patients with secondary Raynaud's was 280 ng/ml. This was highly significantly elevated from those values obtained in our normal population. Again the level did not vary with the duration or activity of the disease process. In addition, the levels obtained in patients with primary Raynaud's and VWF were both significantly elevated from our normal values, although the magnitude of this increase was considerably less than that found in patients with secondary Raynaud's. The median levels found in primary Raynaud's and VWF were very similar, at 12·5 and 17·3 ng/ml. There was no significant difference in the levels obtained in our small group of menstruating women, 14·9 ng/ml, when compared with our other normal subjects.

We have also compared the ratio of the two metabolites. There is no significant difference between the ratio in patients with secondary Raynaud's and the ratio obtained in our normal population. Despite the very high levels of both metabolites in this patient group the median ratios were very similar to those of the normal group, 9·41 and 9·60. In each of the other three groups, patients with primary Raynaud's or VWF and menstruating women, the ratio was significantly elevated in favour of thromboxane B_2.

It is interesting to note that one patient who was originally classified in the VWF group had very high levels of both metabolites, well above the other members of that group. He has subsequently been shown to have a circulating autoantibody and probably has scleroderma. This patient was removed from the VWF group before the analysis of the results.

Platelet aggregation

ADP. Lower doses of ADP were more discriminating between the groups; *Figure 2* shows the extent of aggregation after 3 min for three doses of ADP.

At 2·5 μM ADP, the responses of platelets from normal subjects, patients with primary Raynaud's and patients with secondary Raynaud's were no different with medians all around 50 per cent. The platelets from patients with VWF were significantly less sensitive to this dose of aggregant with a median extent of aggregation of only 34 per cent.

At 1·25 μM ADP, platelets from patients with VWF were highly significantly less sensitive to the aggregant than the normal group. The median extents of aggregation were 12 and 21 per cent respectively. In contrast, at this concentration of ADP, platelets from patients with primary Raynaud's were significantly more sensitive to the aggregant, with a median extent of aggregation of 35 per cent. This trend was even more marked for patients with secondary Raynaud's, with a median extent of aggregation of 52 per cent.

At 0·625 μM ADP, platelets from normal subjects and patients with VWF showed very little response to the aggregant and there was no difference between them. Again patients with primary and secondary Raynaud's showed a highly significantly more marked response to this concentration of aggregant, with median extends of aggregation of 11 and 16 per cent respectively.

In each case the maximum height that the curve achieved reflected very closely the height at 3 min and analysing these results did not add anything to the analysis of the 3 min results. The angle of the steepest part of the curve was an unhelpful measurement, it is imprecise and did not even reliably distinguish the concentration of aggregant used.

Another way of expressing platelet sensitivity to ADP is to find the highest concentration at which aggregation failed to occur. In our normal population this was most commonly 1·25 μM, for patients with VWF the results were very similar. However a significantly lower concentration of ADP was needed before platelets from patients with primary Raynaud's failed to aggregate. The most common concentration needed was 0·625 μM. This trend was even more marked in patients with secondary Raynaud's in whom a concentration of 0·3125 μM was most commonly needed before their platelets failed to aggregate.

Collagen. Measurement of the height of the collagen curve did not reveal any differences between the patient groups but there were differences in the duration of the delay before the onset of aggregation (lag phase). The lag phases in seconds for the 2 mg/l collagen curves are given in *Figure 3*.

At 4 mg/l there were only small differences between the groups although the results reflected the findings using ADP. The median lag phase for platelets from patients with VWF was 77 s, which was slightly longer than that found in the normal subjects, 58 s, but the difference was not significant. The median lag phases for platelets from patients with primary and secondary Raynaud's were 50 and 48 s respectively. These were shorter than that found for the normals and the difference reached significance for the primary group.

The lower of our two collagen concentrations, 2 mg/l, produced a better separation between the groups (*Figure 3*). The median lag phase in our normal subjects was 82 s. Again, although the lag phase for platelets from patients with VWF was longer than this, with a median of 96 s, the difference was not significant. Patients with primary and secondary Raynaud's both had shorter lag phases than the normals, median values were 72 and 61 s respectively. In both cases the difference was significant.

Adrenaline. Adrenaline was an unhelpful aggregating agent, producing a very variable response with no distinction between the groups.

Discussion

As the half-lives of prostacyclin and thromboxane A_2 are extremely short their levels are often inferred by measurement of their stable metabolites, usually 6-keto-PGF$_{1\alpha}$ and thromboxane B_2 respectively.

Absolute levels of 6-keto-PGF$_{1\alpha}$ are best obtained by gas chromotography–mass spectrometry but it is expensive and cannot cope with large numbers of samples[12]. Belch suggests that radioimmunoassay[13,14] is probably the best method for

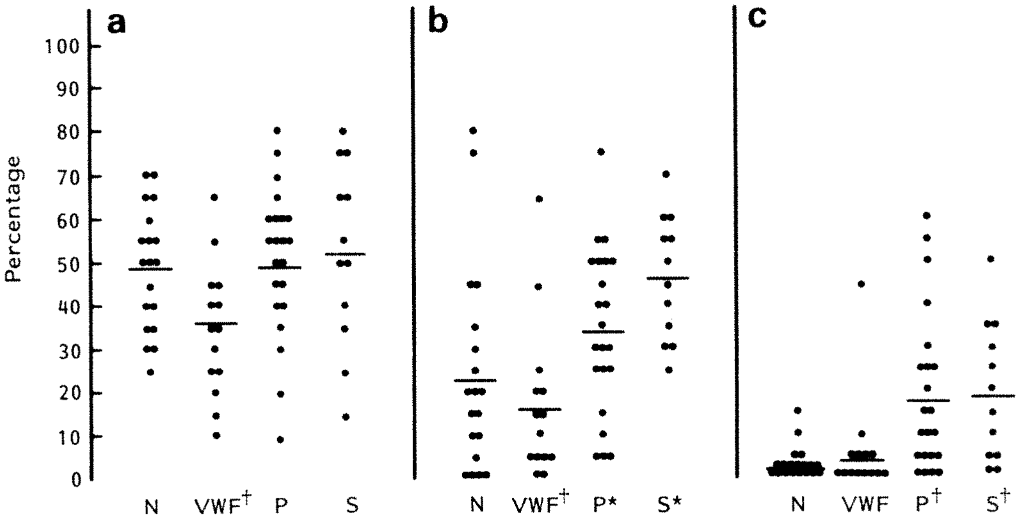

Figure 2 *Extent of aggregation after 3 min (%) to* **a** *2·5 μM,* **b** *1·25 μM and* **c** *0·625 μM three doses of ADP. measuring prostacyclin metabolites in plasma as it is possible to reach a high sensitivity, with good precision and accuracy.

From amongst the controversy regarding the most appropriate measurement technique, and the conflicting results, some consensus regarding methodology has gradually emerged[15–17]. A resting period of 30 min before blood sampling avoids the possibility of raised levels due to psychological stress and physical activity. EDTA or citrate are preferred anticoagulants; heparin should not be used. Traumatic venepuncture is more likely to affect the results than a short period of venous occlusion, although this should be kept as brief as possible. Sample processing at 4°C is useful but if the sample is centrifuged immediately this is not so important. There is likely to be a non-specific increase in the values if the samples are stored for longer than 2 weeks but this effect can be reduced by storage at −70°C rather than −20°C. Repeated freezing and thawing clearly increases immunoreactive material.

These precautions have been carefully followed. The only deviation is that our storage temperature was too high. This may explain the high level of our results when they are compared with the findings of others, but for the purposes of this study we are more interested in a comparison between our patient groups. As all the samples were stored in the same manner a valid comparison between the results can be made but the absolute levels are almost certainly unreliable. It is important to realize that it is impossible to measure resting plasma eicosanoids, as the procedure of venesection and sample processing is bound to raise the levels, despite all precautions. In reality we have performed an eicosanoid 'stress test'.

The finding of high metabolite levels with a normal ratio in patients with secondary Raynaud's cannot be explained but perhaps indicates a fundamental disturbance in prostaglandin metabolism. An increase in the thromboxane metabolite in the other patient groups, without an increase in the prostacyclin metabolite, again cannot be explained. It is unlikely to be secondary to a vasospastic attack as care was taken to obtain all blood samples after an equilibration period in a warm environment.

The platelet results are also difficult to explain. Unfortunately in some studies no distinction has been made between patients with idiopathic Raynaud's phenomenon and Raynaud's syndrome secondary to a connective tissue disorder[18,19] so there is little previous work with which to compare our results directly. This is particularly true for the most surprising of our findings, in patients with VWF. Ikehata[20] found increased sensitivity to a range of aggregating agents in a series of patients with VWF, but these patients included some who suffered from a number of other diseases including peripheral vascular disease whilst the control group only contained healthy subjects. Bovenzi[21] found no abnormalities in platelet function or blood clotting parameters in 22 vibration-exposed foundry workers but only one subject was graded as one on the Taylor–Pelmear scale[11], all the others were graded zero.

When compared with our normal subjects, patients with VWF have an elevated thromboxane B_2 level, with a normal 6-keto-$PGF_{1\alpha}$ level. Their platelets are somewhat surprisingly less sensitive to ADP and collagen. Patients with primary and secondary Raynaud's have elevated thromboxane B_2 levels but this is much more marked in the secondary group. Patients with primary Raynaud's have a normal 6-keto-$PGF_{1\alpha}$ level but in patients with secondary Raynaud's the 6-keto-$PGF_{1\alpha}$ level is also markedly raised. The platelets from both groups are more sensitive to ADP and collagen and this is more marked in the secondary group.

A simple link between elevated thromboxane levels and increased platelet sensitivity is unlikely in view of the diminished response of platelets from patients with VWF to both aggregating agents, especially ADP.

To conclude, we have demonstrated abnormal eicosanoid levels and *in vitro* platelet behaviour in patients with Raynaud's phenomenon. The relationship between these two phenomena is unclear. Platelets both produce eicosanoids and have their function regulated by them. It is therefore impossible to determine if the abnormalities we have demonstrated in platelet behaviour are a cause or an effect of vasospasm.

Out-patient operation of inguinal hernia in children

S. Mejdahl, H. J. Gyrtrup and E. Kvist

Paediatric Section, Department of Surgery, Sundby Hospital, DK-2300 Copenhagen S, Denmark

Correspondence to:
Dr H. J. Gyrtrup, Vejrøgade 6, 2,
DK-2100 Copenhagen Ø, Denmark

A retrospective review is presented of 496 children with a median age of 4 years (range 0–13 years) on whom a total of 527 hernia repairs were performed as out-patients. No wound infections were observed, and the rate of early surgical complications was 1·5 per cent. There were 15 (3·7 per cent) known recurrences. No complications from the anaesthetic were recorded. Owing to the negligible infection rate and the low surgical complication and recurrence rates it is concluded that children with inguinal hernia would benefit from operation as out-patients, and that they should be operated on immediately after diagnosis, irrespective of age. Besides probably minimizing the children's psychological trauma, out-patient surgery provided considerable savings to the health service in the present study.

Keywords: Inguinal hernia, herniotomy, out-patient

The tendency over the past few years has been for out-patient surgery for children wherever possible, the child's admittance period thus being shortened and psychological trauma minimized. Additionally, out-patient surgery may contribute to the curbing of rising costs of health services[1–5].

Since 1980, all herniotomies performed on children at Sundby Hospital have been out-patient procedures performed immediately after diagnosis, irrespective of age.

In the present review, we have assessed the results of these operations to ascertain whether out-patient surgery in this form is surgically and anaesthesiologically justifiable.

Patients and methods

In the period from 1 January 1980 to 31 December 1987, out-patient operation of inguinal hernia was performed on 496 consecutive children with a median age of 4 years (range 0–13 years). Thirty-one children had bilateral hernia, so that 527 hernia repairs were carried out. Sixteen children are included twice, owing to operation for right-sided and left-sided inguinal hernia at different intervals. Age grouping is indicated in *Figure 1* and sex ratio and side presentation are given in *Table 1*.

On the morning of admission, patients were premedicated rectally before being moved to the operating theatre. Anaesthesia was produced with halothane, by face mask; endotracheal anaesthesia was practised only in cases of bilateral hernia. The skin was disinfected twice with 0·05 per cent chlorhexidine solution. Operation was performed by either the department's senior surgeon or a surgical registrar. In all cases, the skin was closed intracutaneously with soft-catgut-plain (B. Braun, Melsungen, FRG). None of the patients received peroperative antibiotic treatment. On full awakening from anaesthesia patients were examined by a paediatrician and discharged with notice to attend the out-patient clinic a week later.

A total of 462 patients representing 508 hernia repairs could be traced. The parents of these patients were sent a questionnaire asking whether the child had undergone a second operation for recurrence of the hernia and whether there had been any other problems regarding the wound. The questionnaire was returned by 366 parents (79·2 per cent), representing 402 hernia repairs (76·3 per cent).

Results

One patient contracted a lesion of the bladder and was admitted for a period of 5 days. One patient developed a scrotal haematoma requiring evacuation, admittance thus being prolonged for 4 days. Nineteen patients remained for a single night: eight of these on sociological grounds, six due to vomiting, three on account of bloody seepage from the wound and a further two with slight temperatures. Three patients were readmitted and reoperated on after 1 day, two of these because of wound haematoma, and the third because of sustained external bleeding. In three patients, the scheduled examination the following week showed minor scrotal haematomas that did not require treatment. No wound infections or scrotal abscesses were observed. According to the hospital records and the questionnaires, no late infections or other wound problems were recorded. The questionnaires revealed 12 recurrences (3·0 per cent) equally distributed among the age groups. From the hospital records another three recurrences were found. The recurrence rate on 406 hernia repairs was thus 3·7 per cent.

Discussion

In terms of age, sex and side of presentation of the hernias, our findings correspond with those of investigations of in-patient

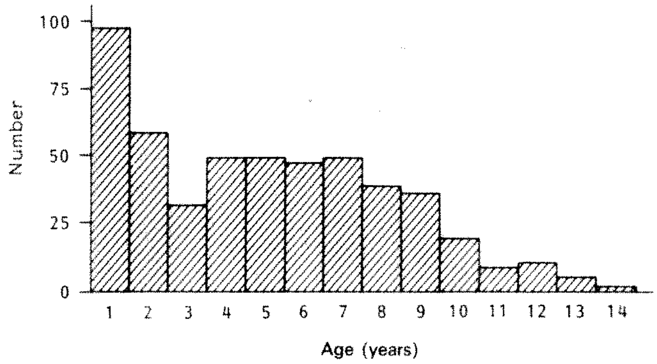

Figure 1 *Number of children treated for inguinal hernia in age groups: 0–1 years, >1–2 years etc. up to >13–14 years*

Table 1 *The side of presentation and sex ratio of 496 children with inguinal hernia*

	Side of presentation			
	Right	Left	Bilateral	Total
Boys	246 (63·9)	124 (32·2)	15 (3·9)	385 (77·6)
Girls	67 (60·4)	28 (25·2)	16 (14·4)	111 (22·4)
Total	313 (63·1)	152 (30·6)	31 (6·2)	496

herniotomy; this also applies to the incidence of bilateral hernia in girls, which is significantly higher than in boys ($P<0{\cdot}0005$)[3,6,7]. Five cases of immediate surgical complications that required treatment occurred, and a further three cases required observation. This gives a surgical complication rate of 1·5 per cent, which also corresponds with other findings. The recurrence rate is no different from that in other studies[3,6–8]. However, as indicated in the results above, none of the patients suffered from postoperative wound infection, which contrasts with in-patient herniotomy of children, where the incidence of infection is recorded as 2·3 per cent[7].

A factor of possible major importance for the negligible incidence of infection in the present study may be that patients were operated on immediately after admittance and discharged on the same day; the possibility of nosocomial infection under these circumstances is assumed to be slight[1,9]. This does not, however, explain why children in nappies, with the possibility of massive faecal fouling of the wound, avoid infection. Better subcutaneous perfusion, and thereby higher tissue oxygen tension, in children could be considered as a possible influencing factor[10,11]. As shown, all the wounds were closed intracutaneously with soft-catgut-plain; this type of suture is possibly less of a tissue irritant than others. Under all circumstances, with intracutaneous technique, skin perforations are avoided and a possible gateway for bacteria is thus excluded. Also of relevance to the low complication rate in the present series is the fact that the operations were performed by experienced surgeons[12].

In conclusion, our results seem to indicate that otherwise healthy children with inguinal hernia can be recommended for out-patient surgery. As there are no differences in wound infection and surgical complication rates between the smallest and the oldest children, and bearing in mind the greater risk of hernial incarceration in the smallest children[8,13], we advise that the herniotomy should be performed as soon as possible after diagnosis. In addition to the probable minimization of the children's psychological trauma, the economic saving was approximately 2·5 million Danish kroner (about £300 000 sterling) in the present series.

Use of the ultrasonic aspirator in splenic preservation

C. P. Nnochiri, M. Rees and R. J. Heald

Department of Surgery, Basingstoke District Hospital, Basingstoke, Hampshire RG24 9NA, UK
Correspondence to: Mr M. Rees

Conservation of splenic function is now generally regarded as a desirable objective in the management of splenic injury or disease[1]. Attempts to preserve a viable splenic remnant have led to various techniques that testify to surgical ingenuity[2–4]. Two cases of hemisplenectomy using the ultrasonic surgical aspirator are presented.

Case reports

Case 1

A 10-year-old boy presented with upper abdominal pain and a mass in the left upper quadrant. Ultrasound examination confirmed a cyst in the lower part of the spleen, with a normal blood picture. The patient's abdominal tenderness led to a semiurgent laparotomy, at which time a partial splenectomy was performed using the ultrasonic aspirator to remove the cyst intact. Blood loss was less than 100 ml and the patient's recovery was uncomplicated.

Case 2

A 34-year-old man was referred with upper abdominal pain and distension. No haemopoietic disorder was found, but ultrasound scanning showed a cyst in the spleen, confirmed by a computed tomography (CT) scan to measure 16 cm. The ultrasonic aspirator was used to perform a partial splenectomy to excise the cyst intact. Blood loss was less than 400 ml and the patient's recovery was smooth except for transient left basal atelectasis.

Technique

After a midline (case 1) or a left subcostal (case 2) incision, the spleen was completely mobilized and its vascular pedicle clearly dissected. Intraoperative ultrasound helped to delineate the cyst margin. The segmental arterial branches were ligated and, after demarcation, the splenic capsule was incised with diathermy. The ultrasonic aspirator was then used to dissect the splenic parenchyma (*Figure 1*), skeletonizing the vessels for easy haemostasis by diathermy and ligation. In the second case, one oozing vessel was stopped by clamping the splenic artery and applying collagen fleece to the raw surface for 5 min.

Discussion

Ultrasonic dissection is well established in neurosurgery and hepatic surgery. Two groups in the USA have recently developed the technique of ultrasonic splenic dissection[5–7]. We wish to support this work by advocating ultrasonic partial splenectomy as a means of preserving splenic tissue.

The essential feature of the Cavitron® ultrasonic surgical aspirator (Sigmacon UK Ltd., UK) used in these cases is a pencil-like, hand-held device whose tip vibrates at high frequency. The hollow tip has continuous suction and an irrigation channel to keep the tip clean throughout. Vibration at the target tissues causes vacuolation and cavitation of nearby cells. The fragmentation of cells is proportional to their water content. The hepatic, splenic and neural tissues are most susceptible, while tissues having a high content of collagen and elastin are relatively protected, except at high power. In this way, blood vessels, bile ducts etc. can be skeletonized as the surrounding parenchyma is fragmented and aspirated, allowing easy and secure ligation or diathermy, depending on size. This avoids the retraction of oozing blood vessels into the parenchyma, usually associated with blunt finger fracture[8].

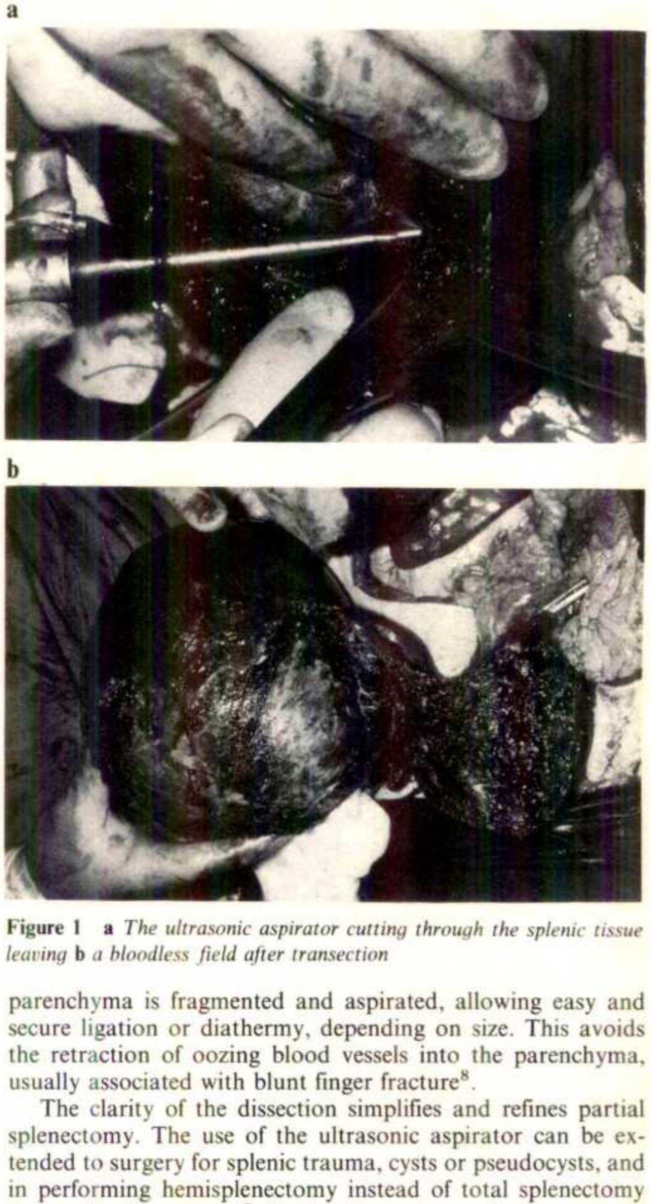

Figure 1 **a** *The ultrasonic aspirator cutting through the splenic tissue leaving* **b** *a bloodless field after transection*

The clarity of the dissection simplifies and refines partial splenectomy. The use of the ultrasonic aspirator can be extended to surgery for splenic trauma, cysts or pseudocysts, and in performing hemisplenectomy instead of total splenectomy for staging laparotomy[9]. In situations where splenic conservation is both logical and desirable, we advocate ultrasonic dissection.

Treatment of chronic hepatic encephalopathy by the progressive suppression of a spontaneous portacaval shunt via the umbilical vein

H. Bismuth and T. Leese

Hepatobiliary Research Group, Faculty of Medicine, University Paris Sud, France
Correspondence to: Professor H. Bismith, Hepatobiliary Unit, Hôpital Paul Brousse, 94800 Villejuif, France

A patient with posthepatitic liver cirrhosis who developed incapacitating chronic hepatic encephalopathy due to spontaneous portacaval shunting is presented. Progressive suppression of a shunt between the portal and systemic circulation resulted in a successful outcome.

Case report

A 67-year-old woman was admitted in February 1988 with incapacitating chronic hepatic encephalopathy. Posthepatitic cirrhosis had been diagnosed 10 years earlier (antigen HBs negative, antibodies anti-HBs and anti-HBc positive), and for the past year she had experienced increasing encephalopathy resistant to medical treatment. She was no longer able to feed or dress herself and could only walk with help. There was no history of ascites or variceal haemorrhage.

On examination she was overweight (90 kg, 1·65 m), slow mentally, with a marked liver flap making it difficult for her to perform even the simplest of daily tasks. There was no jaundice or ascites. The liver was not palpable, the spleen was enlarged and there was a collateral circulation visible on the anterior abdominal wall.

Investigations revealed that the patient was graded C on the Paul Brousse modification[1] of the original Childs' criteria (albumin 28·9 g/l, total bilirubin 35·4 μmol/l, coagulation factors 35–49 per cent of normal). There were no oesophageal varices at endoscopy. Liver ultrasound revealed hepatic atrophy without any focal defects. The portal vein was patent and measured 19 mm at the hilum, and there was splenomegaly and recanalization of the umbilical vein which measured 20 mm in diameter at the liver hilum. Selective angiography confirmed significant spontaneous portacaval shunting, primarily via the recanalized umbilical vein (*Figure 1*). In view of the severity of the encephalopathy we decided to operate to suppress the umbilical vein. Under general anaesthetic a small transverse incision was made midway between the umbilicus and xiphisternum to the right of the midline. The rectus was split and the peritoneum opened transversely. The round ligament containing the large umbilical vein was exposed and a length of No. 4 silicon tubing, through which had been threaded a reinforcing steel suture, was placed around the entire round ligament without attempting to dissect out the umbilical vein. The two ends of the loop were brought out to the skin surface together via a small incision above the main wound.

On the sixth postoperative day the loop was rotated 180° on the skin surface in a clockwise direction. This manoeuvre was repeated daily, thus gradually constricting the umbilical vein. The progress was followed on plain abdominal X-ray, ultrasound and Doppler examinations. The diameter of the collateral was reduced from 20 mm to 8 mm over a period of 2 weeks with a marked reduction in blood flow and a notable improvement in the patient's encephalopathy. Her mental function improved and she was able to walk and feed herself normally.

She has remained well on follow-up 8 months later with no recurrence of encephalopathy. She has not developed ascites or oesophageal varices. The free ends of the sling have been cut just beneath the level of the skin leaving the constricting loop *in situ* around the umbilical vein.

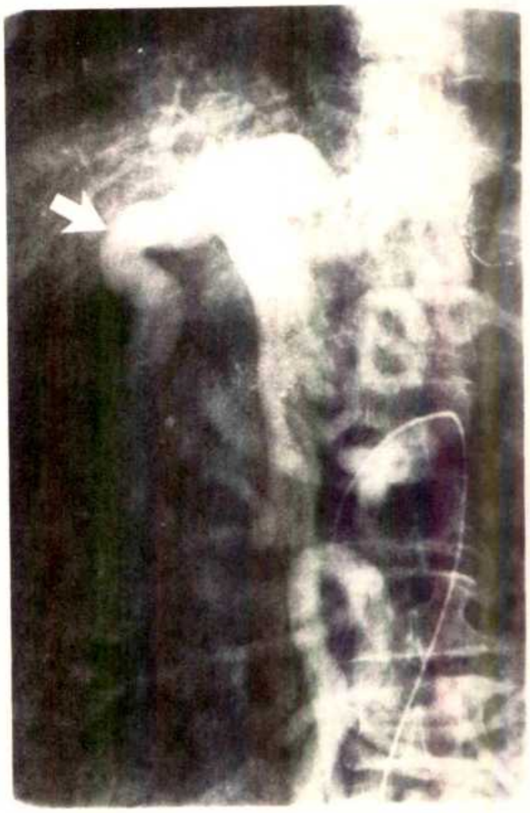

Figure 1 *Venous phase of selective superior mesenteric angiogram demonstrating recanalization of the umbilical vein (arrowed) carrying most of the portal venous blood away from the left portal vein to the systemic circulation*

Discussion

Encephalopathy is a frequent complication of chronic hepatic disease. It is often mild and transient, associated with aggravating factors such as constipation. Severe chronic encephalopathy is usually observed with portacaval shunts, either spontaneous or surgical.

This patient had one principal spontaneous shunt via the reasonably áccessible recanalized umbilical vein. This shunt was suppressed following a relatively minor surgical procedure which was well tolerated despite the patient's major liver dysfunction. The gradual suppression of the shunt enabled the correction of encephalopathy without the development of ascites or oesophageal varices which might have resulted from a sudden increase in portal pressure following complete occlusion of the umbilical vein. It is conceivable that increased portal pressure will result in other spontaneous collaterals opening which may lead to a recurrence of encephalopathy, but after 8 months' follow-up oesophageal varices have not developed and the quality of the patient's life has been transformed by the procedure.

We suggest that in patients with spontaneous hepatic encephalopathy who are not suitable for hepatic transplantation, spontaneous shunts should be identified. In some patients simple surgical suppression of a major shunt may be feasible.

Pernasal catheter perfusion without dissolution agents following endoscopic sphincterotomy for common duct stones

D. F. Martin, J. C. McGregor, M. E. Lambert* and D. E. F. Tweedle*

*Departments of Radiology and *Surgery, Gastroenterology Unit, University Hospital of South Manchester, Nell Lane, Withington, Manchester M20 8LR, UK*

Correspondence to: Dr D. F. Martin

From 80 to 90 per cent of common duct stones can be cleared successfully after endoscopic sphincterotomy[1,2]. This overall figure includes those stones passing spontaneously from the bile duct following the procedure, in addition to those extracted immediately. When stones remain *in situ* after endoscopic sphincterotomy, there is an increased risk of complications[3], particularly cholangitis[4], and consequently a pernasal catheter may be inserted above the stones to ensure drainage and allow cholangiography[5]. The pernasal catheter may also be used to perfuse the bile ducts with dissolution agents such as mono-octanoin[6] and, more recently, methyl-tertiary-butyl-ether (MTBE)[7]. As a controlled study of dissolution treatment via a pernasal catheter after endoscopic sphincterotomy has not been performed, the studies to date are open to the criticism that stones may have passed simply as a result of flushing or drainage rather than dissolution[8]. The current study was performed to determine the effectiveness of perfusion alone.

Patients and methods

Between January 1981 and December 1985, 315 patients with common duct stones underwent a successful and adequate endoscopic sphincterotomy, tailored to the size of the stones. In all patients attempts were made to extract the stones, using an extraction basket and/or a balloon catheter. In 74 patients extraction of all stones was not possible. Failure occurred most commonly when stones, usually in dilated bile ducts, could not be engaged in the basket, or because the balloon catheter slipped around the stones. A 7 Fr wire-guided pigtail catheter (Wilson Cook Medical Incorporated, Letchworth, UK) was positioned above the stones in the bile duct. The catheter was perfused with 2–3 litres of 5 per cent dextrose daily for 3–4 days, at which time cholangiography was performed. When stones were demonstrated, perfusion was continued for a further 4–7 days, after which further cholangiography was performed. If stones were demonstrated, endoscopic retrograde cholangiopancreatography (ERCP) was repeated with attempts at extraction. All patients received a single dose of either mezlocillin 2 g or piperacillin 2 g intravenously before ERCP but antibiotics were not given routinely during perfusion unless clinically indicated. Cholangiography was performed using 30 per cent contrast (Urografin 150®, Schering Health Care, Burgess Hill, UK). Stone size was measured from radiographs with correction for magnification.

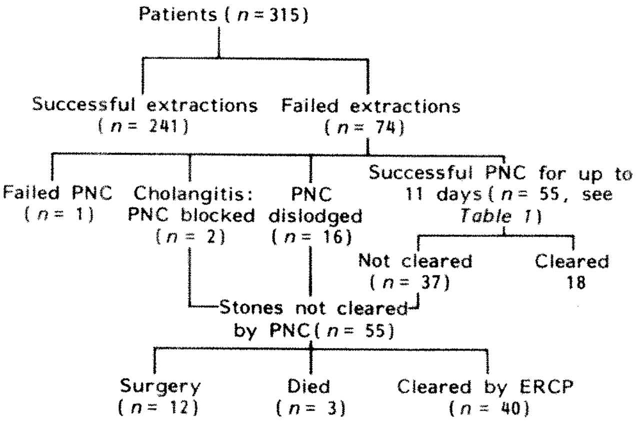
Results

There were 32 men and 42 women with a mean age of 74 years (range 40–94 years). Forty-four patients (59 per cent) presented with obstructive jaundice, 14 (19 per cent) with cholangitis, four (5 per cent) with acute pancreatitis, eight (11 per cent) with biliary colic and four (5 per cent) with postoperative retained stones. There were six complications of endoscopic sphincterotomy but no deaths. Pernasal catheterization was successful in 73 of 74 patients. In one patient the catheter could not be positioned above the stones. Fluoroscopy was performed to check that all catheters remained in a satisfactory position after removal of the endoscope and rerouting of the catheter through the nose. Despite securing all catheters firmly, 16 became dislodged before cholangiography could be performed. Two catheters became blocked, both patients developing acute cholangitis which was treated conservatively. No other complications of pernasal catheterization occurred (*Figure 1*).

Of 55 patients in whom perfusion was completed for up to 11 days, 18 had their ducts cleared of stones: ten after 4 days, a further six after 5–7 days and another two after 11 days. In 37 patients the bile ducts were not cleared of stones. The success or failure of perfusion is compared with the size and number of stones in *Table 1*. As might be expected, single stones and small stones were cleared more readily than multiple and large stones. Of the 55 patients in whom the procedure was unsuccessful (tube dislodged or blocked and failed clearance) 40 had their stones removed subsequently at ERCP, 12 underwent surgery and three died more than 1 month after endoscopic sphincterotomy of unrelated causes before bile duct clearance could be ascertained.

Discussion

This study demonstrates that clearance of unextractable stones after endoscopic sphincterotomy can be achieved by pernasal perfusion with a non-dissolving solution in 33 per cent of all patients in whom the catheter remains *in situ*. Clearance during perfusion is related to the size and number of stones in the common duct. In patients with single small stones 88 per cent clearance was achieved compared with 50 per cent clearance of



Patients (n = 315)
Successful extractions (n = 241)
Failed extractions (n = 74)
Failed PNC (n = 1)
Cholangitis: PNC blocked (n = 2)
PNC dislodged (n = 16)
Successful PNC for up to 11 days (n = 55, see Table 1)
Not cleared (n = 37)
Cleared 18
Stones not cleared by PNC (n = 55)
Surgery (n = 12)
Died (n = 3)
Cleared by ERCP (n = 40)

Total	15	22	3	15	18	37

0007-1323/89/040410-02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

single stones between 0·5 and 1 cm and 12 per cent clearance of single stones bigger than 1 cm. With multiple small stones 33 per cent of ducts were cleared while with multiple medium-sized stones 25 per cent were cleared. There was no success among patients with multiple stones greater than 1 cm. Others[5,6] have reported that pernasal catheters were well tolerated. However, this was not our experience and may relate to the physical characteristics of the fairly rigid polyethylene catheter used in this study which seems to cause nasal and pharyngeal irritation and, we suspect, is frequently dislodged by patients seeking relief from discomfort. Other complications of pernasal catheterization did not occur unless the tube became blocked.

The efficacy of simple perfusion in clearing the common duct after endoscopic sphincterotomy has not previously been reported in a large series, although Cotton *et al.*[5] reported clearance in eight of 17 patients after perfusion following an initial 48-h period of drainage alone, during which time nine of 26 patients cleared stones from the ducts. However, no mention was made of the efficacy of perfusion related to the size and number of stones. The value of dissolution therapy via a pernasal catheter in patients with unextractable stones after sphincterotomy has been reported[6–10]. However, no controlled series has been performed and indeed some authors[8] feel that this would be unethical. In these published series, successful passage of stones has not always been related to the size or number of stones, making assessment of the efficacy of dissolution compared with mechanical flushing difficult. It seems sensible to propose that where single small stones are left in the common duct after endoscopic sphincterotomy, a period of pernasal perfusion without dissolution agents is likely to be successful. However, with multiple larger stones, dissolution therapy, particularly with MTBE, may be preferable. Where access to extracorporeal shockwave lithotripsy is possible, this may offer a potentially less toxic alternative[11,12].

Congenital tracheo-oesophageal fistula in an adult

S. J. Peat, T. Paes, E. R. Howard and P. I. E. Jones

Departments of Anaesthesia and Surgery, King's College Hospital, Denmark Hill, London SE5 9RS, UK
Correspondence to: Dr S. J. Peat

The incidence of tracheo-oesophageal fistula is approximately 1 in 4500 live births. Double fistulae, between the trachea and upper and lower segments of the oesophagus, occur in less than 0·3 per cent[1]. This report describes the management of an adult patient with an undiagnosed proximal fistula who suffered repeated pulmonary complications following aspiration of gastric contents during anaesthesia.

Case report

A 26-year-old Caucasian presented for elective caesarean section and requested general anaesthesia. She had undergone tracheo-oesophageal fistula and atresia repair as a neonate, but was in good health. Physical examination revealed the scars of a right thoracotomy and previous caesarean sections Routine preoperative medication included ranitidine 150 mg and magnesium trisilicate mixture 20 ml orally During rapid-sequence induction of anaesthesia there were no signs of regurgitation After delivery, an orogastric tube was passed, 15 ml of fluid were aspirated and magnesium trisilicate mixture 20 ml was given via the tube, which was then removed Soon afterwards, respiration became noisy and a quantity of fluid, contaminated with medication, was obtained on tracheal suction. On completion of surgery, neuromuscular blockade was reversed and the patient was extubated awake in the left lateral position. Cyanosis and wheezing developed progressively, despite prompt treatment with bronchodilators, physiotherapy and oxygen. Chest radiography revealed patchy shadowing at the left base, and blood gas analysis confirmed the presence of severe hypoxia despite an inspired oxygen concentration of 100 per cent (P_{a,O_2}, 6·5 kPa, P_{a,CO_2}, 3·9 kPa). After 24 h intensive care and continuation of bronchodilator and antibiotic therapy, the hypoxaemia resolved.

Subsequently, the patient admitted to mild dysphagia with attacks of coughing and wheezing at night since childhood, which were worse if she slept with fewer than three pillows and during pregnancy. Review of the medical records showed that oesophageal atresia, confirmed by contrast radiography, had been diagnosed shortly after her birth. Right thoracotomy confirmed oesophageal atresia with distal tracheo-oesophageal fistula and primary reconstruction was performed Postoperatively cyanotic attacks delayed her discharge home, but contrast studies failed to demonstrate a fistula or anastomotic stricture. In her 19th year, a barium swallow investigation showed only a 'web' at the repair site and retrograde oesophageal peristalsis. More recently, there was clinical, microbiological and radiographic evidence of pneumonia following all three previous caesarean sections (one under epidural and two under general anaesthesia) On one of these occasions the lower lobes of both lungs were involved and on the other two occasions only the left lung was involved. Heavy growths of *Streptococcus pneumoniae* and *Haemophilus influenzae* had been isolated from the sputum following her first two caesarean sections. After this latest caesarean section, tracheo-oesophageal communication was suspected and further investigations were carried out

At bronchoscopy a posterior opening, 18 cm from the incisors and well above the original repair, was seen in the trachea. The bronchoscope could be passed through this into the oesophagus. Contrast studies later demonstrated this fistula, but only with cinefluoroscopy and the patient prone. At subsequent operation, a catheter was passed bronchoscopically through the fistula into the oesophagus Through a right transverse supraclavicular incision, the strap muscles were divided and the lower pole of the thyroid retracted superiorly, allowing location and division of the fistula Both oesophageal and tracheal defects were then closed and the patient made a successful recovery.

Discussion

The presentation of an overlooked second proximal tracheo-oesophageal fistula in an adult has not been recorded previously. The clinical features are similar to those described in adults with persistent H-type fistula or a recurrence. Furthermore, most patients with corrected oesophageal atresia and/or tracheo-oesophageal fistula suffer oesophageal malfunction, ranging from minor disorders of motility to severe dysphagia and reflux with recurrent pneumonia[2].

Accurate diagnosis depends on contrast studies and endoscopy. In the presence of the H-type fistulae (5 per cent of all cases of tracheo-oesophageal fistula), contractions of the muscle wall of the fistula[3], the oblique caudal direction of the fistula from the trachea and rapid oesophageal transit may protect the airway from reflux of gastric contents, and may hinder fistula recognition during barium swallow examinations, which should be performed with the patient prone[4]. Bronchoscopy, which is superior to oesophagoscopy in the diagnosis of tracheo-oesophageal fistula, locates the fistula and allows the passage of a catheter through it for operative identification. Since upper pouch and H-type fistulae usually occur above the level of the third thoracic vertebra, surgery can be performed through a supraclavicular incision

The diagnosis of tracheo-oesophageal fistula is sometimes difficult on clinical grounds, and it should be considered after unexplained pulmonary aspiration under anaesthesia, the effects of which might have been ameliorated in this case if non-particulate sodium citrate, rather than magnesium trisilicate mixture, had been used for gastric preparation[5]

Acknowledgements

We would like to thank Mr D Gibb, consultant in obstetrics and gynaecology, for permission to report this case, Dr W. Gardener (Department of Thoracic Medicine) and the staff of the Department of Radiology for their help in the management of this patient

Intervention for graft stenoses: experience following 206 femorodistal reconstructions

J. Thompson, M. McShane, V Gizzard, J. Webster and A. Chant, *Department of Vascular Surgery, Royal South Hampshire Hospital, Southampton, UK*

Femorodistal graft stenoses occur frequently and may progress rapidly to cause graft failure. To assess the incidence of stenoses, 206 patients were studied (74 per cent male, 12 per cent diabetics, mean age 67 years). Ankle brachial systolic indices (ABSI) and Duplex ultrasound were performed 1 month after reconstruction and at 3-monthly intervals thereafter Duplex identified 22 stenoses in 175 grafts which completed serial analyses (105 *in situ* vein, 126 below-knee popliteal or crural anastomoses).

All stenoses were confirmed by angiography. Only five were symptomatic Excluding three early technical lesions, the mean onset was 8 months after reconstruction

Indications for intervention were a fall in ABSI of >0·2, or a haemodynamically high-grade stenosis on Duplex. Treatment was by formal revision or percutaneous transluminal angioplasty (PTA) An initial success rate of 100 per cent was confirmed by angiography and Duplex.

Five of six proximal anastomotic stenoses revised surgically remain satisfactory with a minimum of 1 year follow-up One graft with single vessel run-off occluded at 16 months.

Revisions with PTA performed as follows:

	Proximal $(n=3)$	Intragraft $(n=6)$	Distal $(n=7)$
Recurred (6 months)	3	5	7
Satisfactory (18 months)	0	1	0

Progression of subclinical graft stenoses may be as important as native vessel disease in the aetiology of graft failure. Duplex enables stenoses to be located precisely, so that appropriate treatment can be planned, these data suggest that long-term results of surgical revision are superior to angioplasty

Anticoagulant treatment following vein bypass surgery for femoropopliteocrural arteriosclerosis: influence on patient survival by decreasing the incidence of cardiac deaths

G Kretschmer, E. Wenzl, F. Piza, M. Schemper and E. Gruber, *1st Surgical University Clinic, Alserstrasse 4, A-1090 Vienna, Austria*

The prescribing of anticoagulants for coronary heart disease has been questioned. It seemed promising to test whether anticoagulants might be able to prolong the life of patients suffering from advanced peripheral arterial disease at the femoropopliteocrural level, in which autologous vein bypass surgery was indicated, as cardiac death threatens the life of 50 per cent of these patients The survival status of all patients $(n=1039)$ who had electively received an autologous vein graft during 1970–87 was analysed and Kaplan–Meier estimates were obtained. Ischaemic myocardiopathy alone or in combination with rhythm disturbances played a significant role in decreasing patient survival (median (±standard error of the median) 76·3±4·1 months, no cardiac pathology, 48·8±3·2 months, with cardiac pathology; $P<0{\cdot}0001$ Breslow, $P<0{\cdot}0001$ Mantel). Postoperative anticoagulant treatment influenced the probability of survival in a statistically significant way (median (±standard error of the median) 50·0±2·7 months, no treatment; 117·0±35·5 months, with anticoagulants; $P<0{\cdot}0001$ Breslow, $P<0{\cdot}0001$ Mantel) in particular in the subgroup of patients with cardiac pathology (median (±standard error of the median) 79·3±22·5 months, with anticoagulants; 43·6±3·7 months, without anticoagulants, $P<0{\cdot}0001$ Breslow, $P<0{\cdot}0001$ Mantel). To examine this further, 119 patients who had received a femoropopliteal vein graft at the beginning of 1979 were recruited for a controlled clinical trial and randomly assigned to start phenprocoumon therapy in the second postoperative week (60 patients), or no treatment (59 patients). The median duration of survival for all patients was >60 months, ten patients died in the medicated group and 20 in the control group The treated group had a greater probability of survival ($P<0{\cdot}023$ Breslow, $P<0{\cdot}043$ Mantel) Again, anticoagulants have demonstrated the observed effect by reducing cardiac deaths in the subgroup of patients with cardiac pathology ($P<0{\cdot}018$ Breslow, $P<0{\cdot}028$ Mantel).

Femoropopliteal versus intracrural bypass grafting for limb salvage in patients with an 'isolated' popliteal segment

P.M. Lamont and S.G. Darke (for the Joint Vascular Research Group, UK), *Royal Victoria Hospital, Bournemouth, UK*

Renewed interest in the *in situ* technique has facilitated vein bypass to the distal calf vessels. A degree of doubt exists as to the best site for the distal anastomosis when a patent popliteal artery is 'isolated' from healthy calf vessels by an occluded or significantly diseased intervening segment This multicentre, randomized, prospective trial examines this dilemma.

Fifty-nine patients with critical ischaemia were randomized into two groups· group A, femoropopliteal graft $(n=34)$, group B, femorodistal graft $(n=25)$. All patients had superficial femoral artery occlusions with a patent segment of popliteal artery suitable for grafting seen on arteriography. This popliteal segment had a poor run-off, with either occlusion or stenosis separating it from healthy distal calf vessel(s).

Where possible, *in situ* long saphenous vein was used for bypass, although eight patients in group A and two patients in group B had prosthetic grafts inserted

	Group A	Group B
Primary graft patency	29/34 (85%)	20/25 (80%)
Mean postoperative rise in ankle·brachial pressure index (±s.d.)	0·45±0·29	0·37±0·27
Late graft occlusion (1-year follow-up)	2	3
1-year graft patency in survivors	23/29 (79%)	16/23 (70%)
Limb salvage rate	30/34 (88%)	21/25 (84%)

There were no significant differences in limb salvage or 1-year graft patency rates between the femoropopliteal and femorodistal bypass groups Technical difficulties were encountered more often in the distal group (24 per cent) than in the proximal group (8 per cent). Femorodistal bypass grafting confers no apparent benefit over femoral bypass grafting into a patent popliteal segment, even though the popliteal run-off is impaired or occluded

Influence of smoking and plasma factors on vein graft patency

S.A. Wiseman, G. Kenchington, R. Dain and J.T. Powell (for the Femoropopliteal Bypass Trial Participants)

Interactions between blood-borne factors and arterial grafts may influence patency. Blood samples were obtained 6 months after femoropopliteal vein grafting in 157 patients entered into a multicentre femoropopliteal bypass trial. Cholesterol, lipoproteins HDL, LDL and

0007-1323/89/040413-08$3 00 © 1989 Butterworth & Co (Publishers) Ltd

VLDL, apolipoproteins (a), A1 and B, fibrinogen, the fibrin degradation product D-dimer and the smoking markers carboxyhaemoglobin and thiocyanate were measured The 44 patients with grafts that failed within 12 months were compared with 113 patients whose grafts remained patent for at least 1 year

Carboxyhaemoglobin >2·0 per cent with plasma thiocyanate >70 µmol/litre indicated that 41 patients (26 per cent) were untruthful when they said that they had stopped smoking. Based on smoking markers, graft patency in smokers ($n=72$) was 69 per cent at 1 year by life table compared with 85 per cent in 76 non-smokers ($P<0{\cdot}05$). Surprisingly, increased LDL-cholesterol was associated with improved patency at 91 per cent when LDL-cholesterol was above the median, compared with only 66 per cent in the lower half of the range ($P<0{\cdot}01$) Patients with occluded grafts also had significantly higher mean levels of apolipoproteins (a) and A1. Plasma fibrinogen above the median was associated with a 1-year patency of 66 per cent compared with 89 per cent in patients in the lower half of the range ($P<0{\cdot}001$) On multivariate discriminant function analysis the combination of only two variables, plasma fibrinogen and the smoking marker thiocyanate, correctly predicted subsequent patency or occlusion in 129 of the 157 patients

Smoking markers were more sensitive to the risk of graft failure than the history of smoking, which was often inaccurate Fibrinogen and, surprisingly, low levels of LDL-cholesterol with raised apoprotein A1 were associated with graft failure A more forceful approach to stopping patients from smoking, and perhaps therapy to lower plasma fibrinogen levels, appears justified

Low-dose intra-arterial streptokinase in the management of 202 acutely ischaemic legs

D.R Allen, I.B. Faris, L J Ferguson, J.H. Miller, J. Lloyd and A. Robertson, *The Royal Adelaide Hospital, Adelaide 5000, Australia*

Two hundred and two acutely ischaemic limbs in 192 patients (mean age 69·7 years) have been treated with intra-arterial streptokinase. All patients had angiography on admission. a diagnosis of thrombosis was made in 54 limbs (27 per cent), embolus in 37 limbs (18 per cent) and graft occlusion in 111 limbs (55 per cent) An arterial catheter was inserted after angiography and streptokinase was infused as an initial loading dose followed by a maintenance dose Angiograms were performed every 12 h The streptokinase infusion continued until lysis was complete or until the distal vessels had been cleared Limb salvage was achieved in 165 legs (82 per cent) and 37 legs (18 per cent) were amputated Twenty-nine patients (15 per cent) died in hospital, 21 with salvaged legs and eight after amputation Ninety-two of the salvaged legs (56 per cent) required surgery revision after the streptokinase infusion; 67 had graft occlusions with graft revision after clearing the distal run-off vessels and 18 had thrombosed popliteal aneurysms, which were ligated and bypassed after lysing distal clot Seven were distal emboli that had failed to lyse and required formal embolectomy.

Eight embolic occlusions, eight thrombotic occlusions and 16 graft occlusions had incomplete or no lysis after streptokinase and required amputation Minor bleeding complications occurred in 35 limbs and three arteries were perforated Two patients died from cerebral haemorrhage

We conclude that low-dose intra-arterial streptokinase is both safe and useful in the management of acutely ischaemic limbs and that it may be used to convert a difficult surgical option into an easier procedure by clearing distal vessels before surgery.

Epidemiology of atherosclerotic peripheral arterial disease in a random sample of the general population: Edinburgh Artery Study

F.G.R. Fowkes, E. Housley†, C V Ruckley†, C.C A. Macintyre* and R J Prescott, *Department of Community Medicine and *Medical Statistics Unit, University of Edinburgh, and †Peripheral Vascular Clinic, Royal Infirmary of Edinburgh, Edinburgh, UK*

The Edinburgh Artery Study is the first large-scale epidemiological project examining symptomatic and asymptomatic peripheral arterial disease in a sample of the general population in the UK The aims are to examine. (a) aetiological risk factors, and (b) risks of future cardiac and cerebrovascular events The study consists of. (1) a cross-sectional survey of peripheral arterial disease and cardiovascular risk factors and (2) a cohort study of all subjects The purpose of this paper is to describe the methods and some preliminary results of the cross-sectional survey

An age-stratified, sex-specific sample of subjects aged 55–74 years was drawn from the age–sex registers of ten general practices scattered throughout the city of Edinburgh Of these subjects, 1500 attended a clinic for a comprehensive medical examination Peripheral arterial disease was assessed by completion of the World Health Organization (WHO) questionnaire on intermittent claudication, measurement of ankle brachial systolic pressure ratios using a random zero sphygmomanometer and Doppler probe and a reactive hyperaemic test Information was obtained on the following risk factors age, sex, social class, smoking, dietary history, alcohol intake, blood pressure, personality, glucose intolerance, blood lipids, and various haemostatic and rheological factors

Preliminary results indicate that the prevalence of peripheral arterial disease may be slightly higher than detected in other countries Three per cent had intermittent claudication according to WHO criteria, and 14·4 per cent had an ankle brachial systolic ratio <0·9. Further results will describe the distribution of disease in the population and association with other indicators of cardiovascular disease.

Role of exercise testing in minimizing morbidity and mortality in elective abdominal aortic aneurysm (AAA) surgery

K.T. Moran, B Woods, E R Jewell (and G. Shanik), *Lahey Clinic, Burlington, MA 01805, USA*

The role of exercise tolerance testing (ETT) and aggressive haemodynamic monitoring in minimizing morbidity and mortality in 88 consecutive patients undergoing elective repair of AAA was studied Age was in the range 57–84 years (mean 68·2 years) Ninety per cent of patients had two or more and 40 per cent had three or more of the risk factors: hypertension, cigarette smoking, myocardial infarction, angina, congestive cardiac failure or ventricular arrhythmias. Five patients had previously had coronary artery bypass grafts (CABG) Seventy-five patients had ETT and selected patients had thallium tests. All patients were monitored perioperatively with Swan–Ganz and arterial lines

Fifty-eight patients (77 per cent) achieved ≥75 per cent of predicted maximum heart rate (PMHR) on ETT. Thirteen patients had positive ETT, two of whom had angiography and coronary artery bypass grafting before AAA resection Of the 17 patients (23 per cent) who failed to achieve ≥75 per cent PMHR, six had positive thallium tests On the basis of clinical cardiac status or stress test, 20 per cent of all patients were treated with intravenous nitroglycerine perioperatively There were no deaths Mean hospital stay was 8 days Cardiac complications occurred in four patients (5 per cent) with one myocardial infarction, four ventricular tachycardias All four patients had significant coronary artery disease identified preoperatively.

In this study, ETT with selective thallium testing identified patients with severe occult coronary disease requiring CABG before AAA resection, predicted those patients at high risk of cardiac complications and indicated those patients requiring intravenous nitroglycerine perioperatively

Elevated plasma lipoperoxides in atherosclerosis

M D. Stringer and V.V. Kakkar, *King's College Hospital, London SE5, UK*

Many patients with peripheral vascular disease (PVD) and ischaemic heart disease (IHD) do not show the commonly accepted major risk factors and the mechanism of atherogenesis in these individuals is unknown Considerable *in vitro* evidence now exists to support the role of peroxidized lipids in the pathogenesis of atherosclerosis

We have determined plasma lipid peroxide levels in 100 patients with angiographically documented occlusive arterial disease (50 patients with PVD and 50 with IHD) and in 75 control subjects with no clinical features of atherosclerosis. Lipid peroxide levels, measured by a fluorometric assay, were significantly higher in both patients with PVD (mean 4·55 µmol/litre, s.d. 1·23 µmol/litre) and IHD (mean 4·66 µmol/litre, s.d. 1·27 µmol/litre) compared with controls (mean 3·50 µmol/litre, s d. 1·19 µmol/litre, $P<0{\cdot}0001$) There was no significant correlation within any group between plasma lipoperoxides and either total triglyceride or cholesterol values. Furthermore, hypertension, obesity, diabetes, smoking, positive family history and β-blocker/thiazide diuretic intake were not associated with significant differences in lipoperoxide levels

This study provides the first controlled clinical evidence to support a role for peroxidized lipids in atherosclerois

Laser angioplasty with a pulsed neodymium-YAG laser: initial follow-up of the first 40 procedures

J.A. Michaels, F.W. Cross, P. Shaw, M. Raphael, T.J. Bowker, S.G. Bown, M. Adiseshiah and A. Marston, *University College and Middlesex Medical School and Bloomsbury Vascular Unit, London, UK*

Since December 1986, 40 laser angioplasty procedures have been performed using the energy from a pulsed Nd-YAG laser (Lumonics, UK), delivering near infra-red light (1064 nm) in 100 μs pulses of c. 300 mJ per pulse, directly through a transparent sapphire-tipped device All patients had total occlusions of the superficial femoral arteries and symptoms severe enough to warrant surgery, with ulceration or gangrene in eight, rest pain in 14 and severe claudication interfering with lifestyle in the others. The device was introduced through an antegrade puncture of the superficial or common femoral artery and laser recanalization was followed by attempted balloon angioplasty in all cases Occlusions were a mean length of 16 cm (range 2–35 cm); ten patients had previously undergone failed attempts at conventional balloon angioplasty and four had occluded femoropopliteal grafts. Thirty-seven legs of 34 patients were treated, with successful recanalization in 27 and immediate re-occlusion in seven. An average of 60 J was required (range 10–235 J) The 20 successful recanalizations have been followed up for up to 21 months (mean 8 months) with only one late occlusion at 5 months Failed recanalization was due mainly to poor transmission by the delivery device in the early part of the series (five cases), repeated passage of the device down a collateral branch (four cases), or dissection at the site of previous surgery (two cases) Immediate re-occlusion was due to very poor run-off in patients with severely ischaemic limbs (three cases) or technical difficulties with balloon dilatation (two cases) There were no obvious causes in two cases. Complete symptomatic relief was obtained in all the cases of radiologically successful laser angioplasty Early surgery was required in one case following re-occlusion of the artery when an angioplasty balloon failed to deflate, and one patient suffered a skin reaction thought to be due to inadequate removal of the sterilizing solution, which has since been altered. Laser angioplasty can reduce the number of patients requiring bypass surgery and improvements in device and access methods may reduce the number of untreatable cases

Identification of patients with impaired cerebral perfusion reserve before carotid endarteriectomy

A.R. Naylor, C.V. Ruckley, I. Gillespie, R. Cull, P. Sandercock, C.P. Warlow and M.V. Merrick, *The Royal Infirmary and Western General Hospitals, Edinburgh, UK*

Using positron emission tomography, it has been demonstrated that the most accurate predictor of cerebral perfusion reserve (CPR) is the ratio of blood flow to blood volume, which is the reciprocal of cortical transit time[1].

Previous attempts to apply transit times derived from first-pass data have been limited by a failure to correct for dispersion of the bolus following intravenous injection of a non-diffusible tracer Using a new technique, based on the recognition that transit times are additive[2] and which employs a calculation of the γ variate to determine transit times through the aortic arch and brain, this error is corrected and regional median cortical transit times (MCTTs) are determined. This method has been employed in the serial evaluation of 34 patients undergoing carotid endarteriectomy and identified 15 patients in whom there was significant asymmetry of preoperative MCTTs, suggesting impaired CPR.

Restoration of symmetry was evident in eight of the 15 following surgery, with asymmetry persisting in seven The latter included three patients with contralateral internal carotid occlusion, three who developed postoperative neurological deficits and one patient in whom the asymmetry corresponded to an area of old cortical infarction.

Our preliminary data suggest that this simple method may identify those patients with impaired CPR before carotid endarteriectomy and that those patients with computed tomographic evidence of infarction and impaired CPR ipsilateral to the side of operation may be at higher risk of perioperative stroke

Laser-assisted percutaneous transluminal angioplasty (LPTA): results and complications

E.R.T.C. Owen, S.A. Moussa, R.A. Wilkins and J.D. Lewis, *Northwick Park Hospital and Clinical Research Centre, Harrow, Middlesex, UK*

The enabling event in percutaneous angioplasty is the ability to cross the lesion with a guide-wire. Laser probes under fluoroscopic control have recently been introduced to assist in crossing occluded arterial segments.

Over a 15-month period, 125 patients underwent conventional angioplasty, 22 patients (mean age 72 years, range 50–91 years) have undergone 24 laser-assisted percutaneous transluminal angioplasties All lesions treated were total occlusions distal to the common femoral artery and varied in length from 2 to 40 cm. Laser (Trimodyne 1 5 mm 'hot-tip', Trimodyne Incorporated, Tustin, California, USA) was only used when the occlusion could not be crossed by conventional guide-wire technique. Of the 24 occlusions, eight (33 per cent) could not be crossed with laser; two of the 16 lesions crossed could not be dilated because of vessel perforation Thus, 14 (58 per cent) lesions were dilated; one re-occluded immediately but 13 remained patent, all patients showing signs of revascularization, and improvement in ankle.brachial pressure index in ten. Seven of these re-occluded within 2 months three early (within 24 h) and four late (2 days, 1 and 3 weeks, 2 months) In only six patients the dilated vessel remained patent for up to 1 year.

Complications occurred in 14 (58 per cent of procedures), perforation (8 per cent) and extravasation (36 per cent) are attributable to laser None adversely affected the outcome in the limb except by preventing angioplasty. Laser-assisted percutaneous transluminal angioplasty in its present format has only found a limited place in management The longer distal occlusion remains a problem for the interventionist, as does the long-term maintenance of patency after successful laser-assisted percutaneous transluminal angioplasty

Percutaneous angioscopy of peripheral arteries

A. Gehani, S. Ashley, S.G. Brooks, A.B. Latif, R.C. Kester and M.R. Res, *Cardio-Thoracic Research Unit, Killingbeck, Leeds, UK*

Angioscopy provides a new perspective of peripheral vascular disease. We have used high resolution, ultrathin, flexible fibre-optic angioscopes (1 4 mm and 1 8 mm outer diameter) for percutaneous assessment of seven iliac or femoral arterial occlusions in six patients before and after angioplasty. Procedures were carried out with either a fast rotating tip atherectomy device (Kensey catheter), or sapphire tip modified Nd-YAG laser energy and, in one case, balloon angioplasty alone A clear view was obtained by displacing flowing blood with a high-flow saline flush A microchip camera attached to the eyepiece of the scope provided continuous video monitoring and recording of each procedure

Angioscopic views were compared with pre-, intra-, and post-procedure angiograms Angioscopy identified the pathological nature of stenoses and occlusions (thrombotic or atheromatous) precisely. In addition, angioscopy was more sensitive at detecting the presence of non-stenotic pathology. Angioscopy provides a useful assessment of the initial results of angioplasty. In particular, angioscopy detected intimal flaps and dissections more readily than angiography and, on the basis of this information, additional therapeutic manoeuvres were employed, such as 'laser welding' of obstructive intimal flaps Angioscopy detected fresh thrombus in two out of seven arterial sheaths, despite adequate heparinization.

We conclude that angioscopy complements angiography in the assessment of occlusive peripheral arterial disease, and provides additional information which is particularly useful for guidance and valuation of new percutaneous recanalization techniques

Homologous vein in secondary access surgery

J.J.F. Steijling, R.W.H. Van Reedt Dortland, A. Dimitroff and T. Theodorides, *State University Hospital Utrecht, Utrecht, The Netherlands*

Since 1983, homologous vein grafts have been used in secondary access surgery in the Department of Vascular and Transplantation Surgery of the State University Hospital, Utrecht. One hundred and seventy-six arteriovenous fistulae were constructed with homologous vein in 149 patients with end-stage renal disease The cumulative patency is 73 per cent after 53 months (life-table method).

In 64 grafts (36·4 per cent) 137 reinterventions were necessary because of thrombosis (83), stenosis (30), aneurysmal dilatation (18) and infection (six). No signs of rejection were seen on histological investigation. There was no serious morbidity or mortality related to the fistulae.

Patients, nurses and medical staff prefer these fistulae over other material in secondary access because of easy puncture, low incidence of complications and easy management of any complications.

Computerized storage of angiograms

E. Antebi, J. M. Lehmann and M. Borstein, *Hasharon Hospital, Petach Tikva, Israel*

A computerized system for the storage and enhancement of X-rays has been developed in association with a major electronics firm in Israel. The system consists of an IBM–PC compatible computer, a video-television camera, an optical disk and a television screen. The X-ray pictures are stored on hard disk or diskettes, together with additional information about the patient. The computer can process the pictures to improve contrast and edge enhancement and to enlarge selected parts of the picture, features especially applicable to angiograms. Further improvements are anticipated in the direction of transmission to satellite computers. Access to pictures is easy and fast, and prompt comparison of X-rays is made possible.

Management of unilateral iliac occlusion

S.D. Parvin and P.R.F. Bell, *Department of Surgery, University of Leicester, UK*

Unilateral iliac occlusion may be treated surgically by aortobifemoral, axillofemoral, iliofemoral or femorofemoral bypass. The results of 69 unilateral iliofemoral bypasses performed over a 7-year period have been reviewed. Indications included claudication (21), critical ischaemia (39), previously infected graft (7) and trauma (two). Risk factors included hypertension (20), previous myocardial infarction (eight), angina (11), cerebrovascular accident (nine), diabetes mellitus (ten), cigarette smoking (41) or past history of cigarette smoking (20). The mean age of the group was 61 years (range 16–84 years).

Grafts originated from the common iliac artery (59), from the aorta (seven) or from previous Dacron® (E. I. du Pont de Nemours and Company, UK) grafts (three). They were inserted into the femoral artery (common/profunda/superficial) in 55 cases, into the above-knee popliteal in nine and into the below-knee popliteal artery in five. Thirteen femoropopliteal bypasses, two femorofemoral bypasses and one profundoplasty were performed at the same time.

The 30-day mortality rate was 2 of 69 (3 per cent). At 12 and 24 months cumulative patency was 94 per cent and 86 per cent respectively ($n=45$ and $n=29$). Neither indication for operation nor the patency of the superficial femoral artery influenced outcome. Iliofemoral bypass is as safe and effective as transperitoneal aortofemoral bypass (97 per cent patent at 1 year) and femorofemoral bypass (91 per cent patency at 1 year), and better than axillofemoral bypass. There is no risk of steal from the donor limb as in femorofemoral bypass and no increased mortality or risk of impotence as in transperitoneal aortofemoral bypass. Iliofemoral bypass may be the treatment of choice for unilateral iliac occlusion.

Primary and secondary vascular reconstruction by femorofemoral bypass

S.H. Silverman, P.B. Brown, M.H. Simms, R. Downing, F. Ashton and G. Slaney, *Queen Elizabeth Hospital, Birmingham, UK*

Reconstruction of unilateral iliac artery occlusion can be achieved by many techniques, of which femorofemoral bypass (FFB) is one which has various reported long-term results. We undertook a retrospective review of 102 patients who underwent FFB and analysed the results by life-table methods in two groups. Group 1 ($n=69$) were those in whom no previous surgery for inflow to the leg had been performed. Group 2 ($n=33$) were those having FFB as a secondary reconstruction, a prior procedure having failed. Five-year postoperative cumulative graft patency, limb salvage and patient survival were 80, 78 and 51 per cent, respectively, in group 1, and 41, 52 and 66 per cent, respectively, in group 2. By comparison, in 400 patients undergoing orthotopic aortofemoral reconstruction in our unit during the same time-period the 5-year cumulative graft patency was 79 per cent.

The variation in reported long-term results of FFB arises as some reports are concerned with primary reconstruction only while others cover primary and secondary procedures. The results of FFB for primary reconstructions are comparable to those of orthotopic bypass grafts and therefore support the use of FFB in all patients presenting with strictly unilateral iliac artery occlusion.

Popliteal aneurysms presenting as acute limb ischaemia

M.W. Kissin, R. Pullan, D.J.A. Scott, M. Horrocks and R.N. Baird, *Bristol Royal Infirmary, Bristol BS2 8HW, UK*

Popliteal aneurysms (PAs) should have surgical bypass to a patent tibioperoneal segment before spontaneous thrombosis or embolization eliminates the critical outflow bed. This orthodox approach clearly covers asymptomatic patients who are low risk and who have PAs which are greater than an undefined minimum critical size. What approach should be used when the initial presentation is progressive limb ischaemia and how should an acutely thrombosed aneurysm be investigated?

The outcome of 22 PAs in 19 male patients from 1978 to 1988 was assessed. Streptokinase infusion was employed to clear thrombus in four patients and arteriography and pulse generated run-off (PGR) was used to image and assess adequacy of the outflow tract. Bypass operation was chosen for nine fit patients with large, asymptomatic PA and for ten patients with ischaemia in whom there was adequate run-off.

Symptoms	No. of patients	Outcome		
		Normal	Claudication	Amputation
Asymptomatic	9	9	0	0
Chronic ischaemia	3	2	1	0
Acute ischaemia	7	3	0	4

The results show an increased likelihood of a poor outcome when the leg was acutely ischaemic ($P<0·01$) and when foot pulses were absent ($P<0·01$). Outcome was unaffected by the absence of a popliteal pulse, the presence of a contralateral PA, the material used for bypass or the operative approach.

The combined use of early arteriography with streptokinase infusion and assessment by PGR may give the best chance of selecting patients for successful bypass.

A warning from 12 years of popliteal aneurysm treatment

L. Hands, J. Collin and P.J. Morris, *Nuffield Department of Surgery, John Radcliffe Hospital, Oxford OX3 9DU, UK*

In the 12 years 1975–87, 35 popliteal aneurysms in 26 patients were managed by a specialist vascular surgical service. The treatment outcome has been assessed at recent follow-up of these patients. Twelve aneurysms were symptomless and 23 were causing local discomfort, were thrombosed, ruptured or associated with distal embolization. Twenty-one aneurysms were treated operatively with ligation and bypass grafting and 14 were managed conservatively. Equal proportions of symptomless and symptomatic aneurysms were treated surgically. All five of the symptomless popliteal aneurysms managed conservatively were still symptomless 4–8 years (median 6·5 years) later whereas only four of the seven symptomless aneurysms treated operatively were symptomless 1–2 years (median 2 years) later. Ten (71 per cent) of the legs with symptomatic popliteal aneurysms treated operatively were symptom-free 6 months–9 years (median 6 years) later, compared with only three (33 per cent) of the symptomatic aneurysms managed conservatively, 1–6 years later (median 1 year) $\chi^2=4·97$; $P<0·05$. A deep venous thrombosis occurred in six (29 per cent) limbs after operation on a popliteal aneurysm. We conclude that operative treatment of popliteal aneurysms should be reserved for those which are symptomatic. A symptomless limb can only be made worse by arterial surgery.

Prevalence of significant peripheral vascular disease in the diabetic population

A. Gee, G.C. Moir, S.W.J. Smith and S.G. Darke, *Royal Victoria Hospital, Bournemouth, UK*

An acute thrombotic or infective episode in the limb of a diabetic patient with pre-existing peripheral vascular disease may lead to major amputation Theoretically, this might be avoided by prospective reconstruction if this was undertaken in anticipation of such an event. To estimate the proportion of patients at risk a systematic evaluation by clinical examination and Doppler ankle systolic pressure measurements was undertaken in 162 known diabetics cared for within one general practice catering for 13 500 patients. An ankle:brachial systolic pressure ratio $<0·6$ was arbitrarily taken as an indicator of 'significant' peripheral vascular disease

This was found in one or both limbs of 26 of the patients examined (16 per cent). Only nine of these patients, however, had symptoms of claudication, rest pain or ischaemic tissue necrosis. The mean age of this group was 77 years (range 50–87 years) compared with 55 years in those with ratios >0 6. Of those affected, nine were insulin dependent, 14 were on oral hypoglycaemic agents and three were on diet alone. The low ankle pressures correlated well with the absence of pedal pulses on clinical examination

Sixteen of these patients were referred to a vascular clinic where the distribution of the peripheral vascular disease was determined on clinical grounds. In seven it was thought to be principally infrapopliteal, in five there was evidence of femoropopliteal occlusion, and in four there was aortoiliac stenosis together with an uncertain degree of more distal disease. Where appropriate angiography has been undertaken The possible clinical relevance of these findings is discussed

A prospective study of atherosclerotic renovascular disease causing renal failure: incidence and treatment outcome

G. Hamilton, J.E. Scoble, E.R Maher, R. Dick and J.F. Moorhead, *Royal Free Hospital, London, UK*

Renal artery stenosis from atherosclerosis is a potentially curable cause of renal failure. To date, studies have looked only at selected groups of patients with relatively good renal function referred for angioplasty or surgery This prospective study (at a nephrology centre serving a population of c. 1 million) was carried out over an 18-month period to identify patients with renal failure (creatinine clearance $\leqslant 30\,\mathrm{ml/min^1}$) in whom renovascular disease might be the cause.

Out of 64 patients of all ages, recruited for renal replacement therapy, ten were confirmed by digital subtraction angiography as having renovascular disease as the cause of their renal impairment All ten were >50 years of age, with a mean age of 65·2 years and a serum creatinine of 453 μmol/litre Bilateral disease was present in eight and one had a single functioning kidney Five patients had significant ischaemic heart disease, six had cerebrovascular disease and five had peripheral vascular disease.

Four patients were treated by angioplasty, with significant improvement in one Two patients underwent surgical revascularization, with improvement sufficient to discontinue dialysis in one. Of the remaining four patients, one declined surgery, one had an infarct during angiography and one suffered severe refractory congestive cardiac failure.

This study confirms that atherosclerotic renovascular disease is a common cause of renal failure in patients aged >50 years (29 per cent) In this series, all the patients presented with advanced renal failure and significant improvement in glomerular filtration rate was achieved in only two Although potentially curable, concomitant coronary and cerebrovascular disease makes these patients very high-risk candidates for intervention

Severe finger ischaemia in professional cricketers

D. Wilkinson and R.C. Kester, *St. James's University Hospital, Leeds, UK*

Occupational vibration exposure is a well recognized cause of digital ischaemia but this has not been described in cricketers. Two fast bowlers have recently suffered a rapid onset of rest pain and ulceration in the index finger of their bowling arm. Digital Doppler pulses were absent, rewarming after a cold-stress test was markedly delayed and arteriography confirmed digital arterial occlusion in the symptomatic finger and the adjacent middle finger. The remaining fingers were normal Both were treated with ten daily 8-h intravenous infusions of iloprost, a stable prostacyclin analogue, at a maximum dose of $2\,\mathrm{ng\,kg^{-1}\,min^{-1}}$ In each case the symptoms improved rapidly, and both players resumed bowling.

Two batsmen of a similar age were examined; both regularly field in the slips. Although asymptomatic, both had several absent digital Doppler pulses and rewarming after cold-stress test was markedly delayed in all the fingers of both hands.

The digital involvement may reflect the pattern of occupational trauma, throwing the ball, catching the ball or jarring transmitted through the handle of the bat. The use of iloprost to treat severe occupational hand ischaemia warrants further investigation

Silent myocardial ischaemia in patients with peripheral vascular disease

E.L. Rose, A. Lahiri, E.B. Raftery and J.D. Lewis, *Northwick Park Hospital and Clinical Research Centre, Harrow, UK*

Previous work has shown that only 8 per cent of preoperative patients with peripheral vascular disease (PVD) have no demonstrable coronary artery disease (CAD) on coronary angiography. A significant amount of this CAD is clinically silent with only c 50 per cent having a history of angina.

We assessed 15 preoperative and postoperative vascular patients for evidence of myocardial ischaemia. Eight patients had abdominal aneurysms, five had aortoiliac disease, one had femoral and one had carotid disease. None of the patients had severe cardiac symptoms or would have normally undergone cardiac investigations, seven had a history of angina, of whom three had a previous myocardial infarct.

Reversible myocardial ischaemia, as detected by thallium scintigraphy, was detected in 13 patients but was not predicted by a reduced left ventricular ejection fraction (EF) on radionuclide angiography.

		Thallium scintigraphy reversible defects	
		Present ($n=13$)	Absent ($n=2$)
Angina	Present ($n=7$)	7	0
	Absent ($n=8$)	6	2
Radionuclide angiography	EF $<50\%$ ($n=5$)	5	0
	EF $>50\%$ ($n=10$)	8	2

Of those with positive thallium scans, to date: ten have had coronary angiography confirming severe coronary disease; five have gone on to coronary artery bypass grafting, with one waiting; and one has had coronary artery angioplasty

These data demonstrate the high prevalence of silent myocardial ischaemia in patients with PVD. Over 50 per cent of perioperative deaths are due to CAD; if they are to be reduced, all patients with CAD should be identified and treated accordingly before operation is considered The absence of a history of angina does not exclude reversible myocardial ischaemia

Ultrasound scan screening for abdominal aortic aneurysm

C.S. Loh, I.M. Stevenson, A.V.O. Wu and B. Eyes, *Walton Hospital, Rice Lane, Liverpool L9 1AE, UK*

A group of 1293 men >55 years old were invited to take part in an ultrasound scan screening programme for abdominal aortic aneurysms (AAAs). Six hundred and fifty-seven men attended for scanning (50 8 per cent) Their age ranged from 55 to 94 years (mean $=63$ years 11 months) The abdominal aorta was not visualized in 19 individuals because of excessive bowel gas and in one because of gross abdominal lymphadenopathy Maximum abdominal aortic diameter ranged from 11 to 52 mm (mean $=20$ 1 mm). AAAs (maximum diameter >30 mm) were found in 19 individuals (2·9 per cent) The prevalence of AAAs in this study was 1·3 per cent in the group <65 years old and 6 5 per cent in the group >65 years old. Follow-up scan had so far shown progression in the size of the AAA in one individual. One patient had undergone successful surgical resection and grafting and two other patients had since died. Ultrasound scan screening for AAAs is practicable but should be directed to the population aged >65 years to improve cost effectiveness. Follow-up scan of small AAAs will provide further knowledge regarding the natural history of this condition.

Results of ultrasound follow-up of 102 abdominal aortic aneurysms

R.A.P. Scott, H.A. Ashton, D.N. Kay and R.C. Bowyer, *St. Richard's Hospital, Spitalfield Lane, Chichester, West Sussex, UK*

The study has now identified 102 patients with an aorta $\geqslant 3$ cm out of 2056 patients screened Sixty-nine of the 102 have had repeat scans and 25 have shown an increase in diameter on repeat scan. Twenty have been invited to come to outpatient clinics after their third scan to explain the findings and the reasons for further scans. Ten have reached the criteria for considering surgery (i.e. an aortic diameter ≥6 cm, an increase in diameter of >1 cm per year or the onset of symptoms) and seven have undergone surgery, all with a good outcome. Three were assessed and found to be unfit for planned surgery and continue to be observed. Conversely, 95 with aortic dilatation ≥3 cm have not undergone surgery. None of the patients screened has died of ruptured abdominal aortic aneurysms, although nine have died of other causes.

As a result of this study it seems likely that it is possible to identify: (a) a high-risk group that may require surgery (25 that increased in size on repeat ultrasound scan and those ≥6 cm), (b) a low-risk group (77 who did not increase in size and 1954 who had an aorta <3 cm) who should not require surgery.

Abdominal aortic aneurysms (AAAs): a familial disease

J. Collin and J. Walton, *Nuffield Department of Surgery, John Radcliffe Hospital, Oxford OX3 9DU, UK*

One hundred patients (97 men) undergoing surgery for AAA were interrogated about their first-degree relatives.

One father and four mothers were still alive and one patient had never known his parents. Of 295 siblings, 132 were known to be dead (77 men). Sixty-eight surviving siblings were not available for study and 29 were excluded because they were either >80 years old, or were men <50 years or women <55 years old. Sixty-six siblings were invited for ultrasound examination of the aorta and 27 (41 per cent) attended.

No female relative was known or discovered to have an AAA. Of 132 men who died aged >50 years, three (2·3 per cent) were thought to have died from a ruptured AAA. One of the 57 surviving brothers aged >50 years, who was not examined, was already known to have an AAA. Four AAAs were discovered in 17 men who attended for ultrasound examination and three of these (diameter 4·7–8·5 cm) have since been resected.

Hearsay evidence from AAA patients suggested that the prevalence of AAA in 207 male first-degree relatives who lived beyond 50 years was 1·9 per cent. Ultrasound examination of one in 12 of these relatives revealed an additional unsuspected prevalence of 23·5 per cent. These findings provide strong support for the view that AAA is a familial disease.

Aneurysm surgery in octogenarians

I.C. Currie, D.J.A. Scott, P. Vowden, R. Phillip, K.R. Poskitt, R.N. Baird and M. Horrocks, *Bristol Royal Infirmary, Bristol BS2 8HW, UK*

To justify surgery in the octogenarian there must be a low perioperative mortality and a reasonable postoperative mortality.

We have studied 33 octogenarians undergoing aortic aneurysm repair (14 elective, 19 emergency) between 1980 and 1988 at the Bristol Royal Infirmary. Survivors were given a structured interview at home (I.C.C.) to assess quality of life, which was compared with that of age and sex matched controls.

	Elective	Emergency	Total
Number of patients	14	19	33
Operative mortality	1 (7%)	7 (37%)	8
Late mortality	3 (21%)	8 (42%)	11
Survivors	11	11	22
Mean survival	677 days	818 days	
Range	4–72 months	7–67 months	

In the elective group there was a low operative mortality and a good postoperative quality of life. In the emergency group mortality was not different from younger patients operated on during the same period, and of the ten emergency patients interviewed eight reported having a good quality of life.

Twelve postoperative aneurysm patients were compared with 12 similar control subjects taken from an age and sex matched general-practice population. The incidence of angina, breathlessness, previous stroke, impaired mobility, performance of daily activities, emotional problems and support did not differ between patients and controls.

Aortic surgery, both elective and emergency, cannot be denied to octogenarians on the basis of age alone. These elderly arteriopaths can obtain good direct surgical benefit while remaining independent.

Fibrinolytic enhancement versus surgical ablation of superficial incompetence in the prevention of venous ulcer recurrence: a controlled clinical trial

K.G. Burnand, M.C. Stacey, G.T. Layer, K. Lloyd, F. deBeaux and N.L. Browse, *Department of Surgery, St. Thomas' Hospital, London, UK*

Stanozolol, an anabolic steroid known to enhance fibrinolysis, has been shown to reduce perivascular fibrin deposition and to improve lipodermatosclerosis (pigmentation and induration) in limbs with severe venous disease[1]. It is not known if this improvement in the skin reduces the risk of future ulceration.

Sixty-nine patients have been enrolled in a randomized trial to compare surgery and elastic stockings with stanozolol and elastic stockings in the prevention of ulcer recurrence. Surgically treated patients had all sites of superficial valvular incompetence eradicated. Foot volumetry and phlebography were carried out in all limbs to confirm the presence of venous disease, and other causes of ulceration were carefully excluded. Patients in both groups were well matched for the number of previous ulcers, the longest period of unhealed ulceration and evidence of a previous deep vein thrombosis, all of which appear to influence the likelihood of breakdown.

Eight patients out of 38 treated by stanozolol, and six patients out of 31 patients treated by surgery, have developed new ulcers within 4 years of entry. There is no statistical difference between the number of ulcer recurrences in the two randomized treatment groups, $P = 0{\cdot}1$. Ten of the 20 patients who refused to enter the study and who were treated by stockings alone have already developed new ulcers.

Stanozolol and stockings appear to be as efficacious as surgery and stockings in preventing the recurrence of venous ulceration.

A new approach to chronic venous ulcers in the community

C. Moffatt, D.D.I. Wright, D. Besley, C.N. McCollum and R.M. Greenhalgh, *Department of Surgery, Charing Cross Hospital, London, UK*

At least 150 000 patients suffer venous ulcers in the UK, many failing to heal for months or years, costing £2500 per ulcer per patient per year. A four-layer bandage (4LB) technique provides sustained graduated compression with 40 mmHg at the ankle, which heals most ulcers by 12 weeks, but few patients benefit while treatment is confined to hospital practice.

A 12-week trial clinic linked to a vascular unit was established at a local group practice, all staff were trained in the 4LB technique and volunteers were recruited to help transport patients.

In a population of 7500, 21 (0·28 per cent) patients with leg ulcers were identified, with a mean age of 78 (range 52–91) years and average ulcer duration of 21 months. Venous and arterial disease were assessed by Doppler and three patients with ankle pressure indices <0·8 were unsuitable for the 4LB. The remaining 18 patients attended or were brought by volunteers to the community clinic at the general practitioner's surgery. After 12 weeks, all but two ulcers were completely healed, with a mean time to healing of 3·9 weeks, and patients were then fitted with class 2 compression stockings (DuoMed®, Medi UK Ltd., Hereford, UK). In the 4 months after the trial the remaining two ulcers have healed and there have as yet been no recurrences.

This pilot study demonstrates that multilayer compression bandaging is applicable in the community. The majority of chronic leg ulcers can be healed and the potential savings in resources are considerable.

Fibrin clearance and calf pump function

H. Gajraj and N.L. Browse, *St. Thomas' Hospital, London SE1, UK*

The tissue and blood fibrinolytic activity of patients with venous leg ulceration is reduced. Fibrin cuffs are found around the capillaries of affected skin and these are thought to block the diffusion of oxygen. It is unclear whether this reduction in fibrinolysis is generalized and whether it is related to calf pump function.

Radioactively labelled (^{125}I) fibrin microclots were formed subcutaneously in the arms and legs of 33 subjects with healed venous ulcers, ten subjects with bilateral varicose veins and 11 healthy controls by the injection of 0·05 ml fibrinogen and thrombin. The clearance half-life was calculated for each site. The calf pump function of all subjects was assessed by foot volumetry, measuring the relative expelled volume (EV_{rel}) after 20 knee-bends and the half-volume refilling time ($TV_{\frac{1}{2}}$) at rest.

	Fibrin clot half-life in hours (mean ±s.d.)	
	Arms	Legs
Controls	16·9±5·3	18·1±5·3
Subjects with varicose veins	16·7±2·3*	24·7±6·5†
Subjects with healed ulcers	17·2±3·5*	
Non-ulcerated		25·1±8·9‡
Ulcerated		36·9±21·1§

Compared with control, Mann–Whitney *U* test. *not significant; †$P<0·05$; ‡$P<0·01$; §$P<0·001$

A significant negative correlation was found between the fibrin-clot clearance half-life and $TV_{\frac{1}{2}}$ ($r_s=-0·27$, $P<0·01$). The correlation between the fibrin half-life and EV_{rel} was not statistically significant.

Fibrin clearance is prolonged from the legs only and is related to the degree of calf pump dysfunction

Early clinical results after implantation of a small-bore elastomeric prosthesis

W.F. Tait and D. Charlesworth, *University Hospital of South Manchester, Manchester, UK*

For patients who have pre-gangrene of a leg, no saphenous vein, and in whom a femorodistal bypass has failed there is little alternative to amputation.

We have used a new 4 mm diameter elastomeric prosthesis as a bypass in 24 such limbs In seven, a bypass (polytetrafluoroethylene) had failed and in seven a femoropopliteal bypass with vein had failed In the remainder the vein was either unsuitable or had been removed for a coronary artery bypass graft

Eight bypasses occluded early, and all were characterized by (a) femorotibial bypass, (b) single vessel run-off; (c) ankle:arm ratio unmeasureable One infected but patent graft was removed Fifteen bypasses have remained patent, the longest for 13 months (mean 7 months) The mean (±s.d.) ankle:arm ratio was 0·3±0·1 before operation and 0·76±0·2 after operation. Six of the 15 femorodistal bypasses were done in conjunction with a proximal (iliac) reconstruction.

Preliminary results suggest that a 4 mm elastomeric graft can work in circumstances where currently available prostheses may not

Chronic lower-limb venous insufficiency: an approach to management

P.E. Kiely, *Bon Secours Hospital, Cork, Ireland*

Using a live display of lower-limb venous manometry, the initial part of this programme illustrates normal venous haemodynamics at rest and during exercise This contrasted with the abnormal ambulatory venous pressure response in a limb with venous insufficiency (VI) By way of graphics and manometry the normal muscle pump mechanism is demonstrated. The different ways by which the muscle pump is compromised are shown VI is defined and its pathological consequences are discussed A classification of limbs with venous insufficiency is proposed simple varicose veins, complicated varicose veins; mixed venous insufficiency, post-phlebitic limb

The second part of this programme illustrates the approach to management Since the scope of surgery is limited to the removal of incompetent superficial veins the initial surgical endeavour is directed towards accurate anatomical diagnosis of all superficial incompetences so that surgical ablation will be complete In clinical examination particular emphasis is placed on the importance of pattern in the display of varicose veins as a guide to the incompetent systems and to the identification of perforating veins. Use of the Doppler probe as an essential adjunct to clinical diagnosis is demonstrated The operative techniques of ligation and stripping are shown briefly

Lastly, the importance of functional evaluation of limbs with deep venous insufficiency is demonstrated with particular emphasis on the value of tourniquet walking pressure in identifying those limbs with significant superficial incompetences In this way superficial and deep venous function are differentiated so that no limbs are denied the benefit of surgery to the superficial veins, nor are any subjected to unnecessary operation.

The programme is based on experience in the surgical management of >3000 limbs

Leucocyte trapping in the peripheral circulation in response to changes in venous pressure

H.J. Scott, P.D. Coleridge Smith and J.H. Scurr, *Middlesex Hospital, London, UK*

Leucocytes become trapped in lipodermatosclerotic skin in patients with chronic venous insufficiency (CVI). Is this effect produced by a rise in venous pressure associated with CVI?

Patients with normal deep veins ($n=10$) and CVI ($n=10$) were studied using direct venous sampling from the dorsal foot and hand veins, and dynamic capillary video microscopy of ankle skin Subjects rested supine for 30 min, then sat with the lower limbs dependent for 60 min to raise the venous pressure, and finally lay supine for a further 30 min. In another ten patients, blood was taken from a dorsal hand vein and cephalic vein of the forearm, initially with the arm supine, then dependent for 15 min and finally with a cuff applied to the upper arm at 80 mmHg for 15 min. The results were as follows

Examination	Group	Supine 30 min	Dependent 60 min	Supine 30 min	*P*
Capillill loops per square nanogram at ankle	CVI	10·4(2·0–29)*	8·3(2·0–17)*	12·3(1·0–22)	*0·021
Leucocyte loss (%)	Foot CVI	2·8(−12–17)*	−0·3(−22–13)*	−6·2(−4·9–7)	*n s
Arm measurements		Supine	Dependent (15 min)	Cuff (80 mmHg)	*P*
Leucocyte loss (%)	Fore-arm	0*(ref value)	−1·1(−8·0–1·8)	12(2·7–20)*	*0·006
	Hand	0*(ref value)	−4·9(−10–0·1)	11(−11–31)*	*0·044

All values are given as median and range in parentheses Significance by Wilcoxon paired test

Raising the venous pressure in the arm to 80 mmHg caused white cell trapping in both the hand and forearm. Leucocyte trapping in the feet did not occur although the reduction in functional capillary loops confirms that microvascular changes have occurred in CVI legs The venous pressure rise in response to dependency was too small to influence white cell trapping in the feet.

Randomized study of carotid endarteriectomy versus saphenous vein bypass in the treatment of extracranial cerebrovascular disease

M.C. Crowson, M.X. Gannon, T.I.M. Gardecki and J.D Hamer, *Queen Elizabeth Hospital, Birmingham, UK*

Endarteriectomy has generally been abandoned in vascular reconstructive procedures in favour of autogenous vein or prosthetic bypass grafts. However, endarteriectomy remains the commonest vascular procedure for internal carotid stenosis. Reported restenosis and occlusion rates vary from 1 to 49 per cent; our own experience demonstrated an 18 per cent occlusion rate We have previously reported a pilot study of 37 consecutive vein bypass grafts

We now report a prospective randomized study comparing vein bypass grafts to endarteriectomy in 76 patients (vein bypass 39, endarteriectomy 37) All patients had a postoperative Doppler ultrasound scan which was repeated at 6 weeks Follow-up was then performed at 3-monthly intervals using clinical assessment and Doppler ultrasound scanning, and at 6-monthly intervals using digital subtraction angiography.

To date, the mean follow-up is 14 months. One patient died postoperatively from a myocardial infarct At 6 weeks follow-up six (16 per cent) of the endarteriectomies were occluded and one (3 per cent) vein graft Further follow-up demonstrated that the overall occlusion and stenosis rate was 24 per cent for endarteriectomy and 10 per cent for vein grafts Neurological events (transient ischaemic attack/cerebrovascular accident) occurred in 14 per cent of the endarterectomy patients and 5 per cent of the vein grafts.

These preliminary data suggest that vein bypass may be a superior procedure for the treatment of symptomatic internal carotid stenosis.

Penetrating trauma to the carotid vessels: Lebanese war experience

G.S. Khoury and H. Hajj, *American University of Beirut, Lebanon*

Between April 1975 and July 1987, 510 neck injuries were treated at the American University of Beirut Medical Center The carotid vessels were involved in 48 patients, resulting in 53 carotid injuries.

The mean age was 25·3 years; shrapnel injuries were the commonest (46 per cent) followed by bullet injury (33 per cent), 39 patients had a laceration and five had complete disruption Only three presented as acute arteriovenous fistula (AVF) Neurological deficit was present in 13 patients, of whom six were in coma.

Shock was present in 14 patients, of whom five had a neurological deficit Six patients underwent ligation of the injured vessels, three of which were external carotid arteries. Nine patients were not operated on initially, six of them had chronic AVF and three were in coma; the rest underwent surgicl repair.

Nine patients died, giving an overall mortality rate of 19 per cent, four of these patients died due to complications of multisystem failure, giving a 10 per cent mortality rate for isolated carotid injury There was definite improvement in the repaired group, but the haemodynamic status seemed to affect the mortality rate significantly ($P<0.01$) Follow-up of the surviving patients revealed five with persistent neurological deficit in the repaired group (33 patients) and four patients had chronic AVF, only two patients had false aneurysms.

Annual General Meeting of the Vascular Surgical Society of Great Britain and Ireland

The Annual General Meeting of the Vascular Surgical Society of Great Britain and Ireland will be held on 23–24 November 1989 in Dundee, UK. For information contact, Mr James Forrester, Department of Surgery, Ninewells Hospital, Dundee DD1 9SY, UK

Subtotal colectomy or colonic preservation in the treatment of colonic cancer?

Sir

The paper by Marston (*Br J Surg* 1989; **76**: 71) proposes many arguments in favour of subtotal colectomy with ileorectal anastomosis as the treatment for colonic cancer. He justifies this by claiming that the function of the colon is to absorb water and that loss of the colon results in diarrhoea which can usually, but not always, be controlled by diet and drugs. Whilst the absorption of water and electrolytes has been accepted as the main function of the colon it now seems likely that our knowledge of colonic function is far from complete. Jackson[1] proposed that the human colon, with its normal colonic microflora, might well play a significant part in human nutrition and metabolism. Some of our recent studies have centred on the role of the colon in nitrogen metabolism[2,3]. The human colon is relatively inaccessible and we have taken advantage of the colonoscope to gain access to the lumen of the intact colon. We have inserted labelled urea (^{15}N stable isotope) through the biopsy channel of the colonoscope as a marker of colonic nitrogen metabolism. We have demonstrated that the colon is permeable to urea, that intraluminal hydrolysis occurs and that significant proportions of urea nitrogen can be incorporated into the body pool of nitrogen. The majority of the previous work on colonic function, including colonic nitrogen metabolism studies[4], has been using perfusion techniques following peroral intubation of the caecum. This has entailed preliminary cleansing of the colon followed by perfusion of large volumes (of the order of 10 ml/min) of the solution in question. When one considers that the normal intestinal transit time is 60–72 h and that 40–60 h of this are spent in the colon[5], these perfusion studies may well give misleading results in terms of normal colonic function. The expanding field of research on the metabolism of fibre in the colon[5] and the more recent work on nitrogen metabolism strongly suggest that much further work needs to be done before definitive conclusions can be reached about colonic function. Without this information the prophylactic removal of normal colon has to be a point of considered clinical judgement and it has yet to be proved that it is in the best interests of a patient with colonic cancer.

Severe intra-abdominal sepsis

Sir

I read with interest the paper by Mr Huizinga and colleagues which compares single agent antibiotic therapy with combination therapy in what the authors define as 'severe intra-abdominal sepsis' (*Br J Surg* 1988; **75**: 1134–8). I would like to object to the use of the term 'severe' in the context of their study.

What is the cohort of patients looked at? It included practically every single patient with peritonitis seen over the study period who required laparotomy. The only patients excluded were those allergic to the antibiotic agents and 'those who appeared moribund'. The median age of these patients is only about 30 years. When the origin of the intra-abdominal sepsis was investigated more carefully, it was found that in no less than 78 per cent of cases, the infection originated from gastroduodenal perforations, and traumatic injuries to the small bowel and the appendix. Furthermore, in only 10 per cent of cases was the source of sepsis the colon or the pancreas. None of the patients suffered from postoperative peritonitis. In support of their contention that the abdominal sepsis was 'severe', the authors report the following criteria: delay between diagnosis and treatment, amount of fluids used for resuscitation, tachypnoea, hypoxaemia, acidosis and clouded sensorium which existed in 69 per cent of their patients. The overall mortality rate in these patients was a mere 3 per cent.

Although there is no strict definition of what constitutes severe intra-abdominal sepsis the current trend is to accept as 'severe' sepsis the following: firstly, that which originates owing to factors such as postoperative leaks, the colon and infected pancreatic necrosis (the majority of the patients considered in this trial would fall into the category of relatively less severe peritonitis[1,2]); secondly, most studies of severe peritonitis include a large proportion of patients compromised by old age, intercurrent chronic disease and established organ failure, the mortality of such patients being in the order of 30 per cent[3], which is in sharp contrast with the 3 per cent quoted by the authors. This last figure most certainly suggests an APACHE II score of less than 10 in most of their patients, reflecting the minor physiological insult of the infection on relatively young and previously healthy organ systems[4,5]. Such parameters as hypoxia, tachypnoea or clouded sensorium should have been graded objectively in this prospective trial.

I wish also to point out that when 'all skin wounds were managed by delayed primary closure' it is difficult to understand how wound infections were reported in 11 patients. Is the failure to achieve a delayed primary closure considered a wound infection or is it a secondary infection of the wound left open?

With the kind permission of the authors I wish to suggest the following conclusion to their otherwise excellent trial: adequately treated intra-abdominal generalized sepsis occurring in young patients and originating from perforated peptic ulcers and injuries to the small bowel and from the appendix have a negligible mortality, independent of the antibiotic regimen used.

Surgical aspects of a district hospital combined gastroenterology clinic

Sir

The article by Holmes *et al* on 'Surgical aspects of a district hospital combined gastroenterology clinic' (*Br J Surg* 1988, **75**: 1105–7) was surely meant to be provocative! The fall in operation rate from 35 per cent to 20 per cent is attributed to a reduction in the numbers of certain operations (e.g. operation for peptic ulcer), but there is no mention of the impact of new technology.

In our hospital, diagnostic endoscopy has largely replaced the barium meal: it provides previously unobtainable information about the bile ducts and pancreas, and resolves many problems in the colon. Therapeutic endoscopy is used in the upper gastrointestinal tract (dilatation of benign oesophageal strictures, palliation of gastro-oesophageal cancers, injection sclerotherapy of varices and balloon dilatation of achalasia), in the biliary tract (endoscopic sphincterotomy and extraction of bile duct stones, palliation for malignant strictures and dilatation of benign strictures) and in the colon (endoscopic polypectomy). Most of the patients treated by these methods would formerly have required surgical operations

Therapeutic radiological procedures have also contributed to the reduction in operations (e g treatment of intussusception, percutaneous transhepatic biliary stenting, ultrasound guided biopsy of liver masses and drainage of abscesses and pancreatic pseudocysts)

Anyone considering the formation of a combined gastroenterology clinic in 1989 needs to take account of these technical developments and decide how to distribute this workload between physician, surgeon and radiologist

Diagnosis and management of abdominal pain

Sir

In the recent paper on the use of advisers in the diagnosis and management of patients with abdominal pain (*Br J Surg* 1988, **75** 1173–5), the authors report 711 patients who were admitted with acute abdominal pain. They draw the conclusion that advisers were unnecessary until the patient was admitted. The figures used to support this conclusion are based on just over 50 per cent of the series The exclusions were for a variety of reasons, including the absence of a record of a second opinion or a recorded diagnosis. This might cast some doubt on the conclusions

The reader is left with the impression that the policy of the unit was restricted to a decision whether to admit or not rather than to come to a probable diagnosis which, in turn, would suggest appropriate investigations The sceptic might consider that there were other reasons for admission than the exact requirements of the individual patient

The authors draw attention to the paradox of the inability of the senior house officer to admit a patient without obtaining a second opinion as compared with the power to discharge a patient without such advice. Such a policy is wide open to misuse and leads to inappropriate admission or discharge Unfortunately, there is no list of final diagnoses of the patients who were admitted, let alone those who were discharged. Most of the given references included all patients seen.

The authors state that the majority of patients were admitted, although no percentage is given. What was the majority? It has been shown in the references that it is a common finding that 90 per cent are admitted, but when the system is subject to audit with or without computer diagnosis it is found that the more appropriate figure for admission is around 60 per cent[1] Such a change would free an enormous number of beds. Our own earlier work has confirmed this and after 16 000 patients seen consecutively in our accident and emergency department, all with acute abdominal pain and computer-assisted diagnosis, the figure for admissions remains around 60 per cent[2] It is also clear that the number of re-referrals remains lower than it was before the policy was introduced Similar figures have been reported from many centres in the world

In the light of our experience, we would disagree with the conclusion that the use of the computer-assisted system would be more effective than a second opinion We believe that the computer should not be considered as an alternative to a proper clinical opinion It has been shown by us and many others that the computer is more accurate than the senior house officer who is not using the system However, more importantly, the doctor using the computer system is disciplined to take a more appropriate history and to examine the patient more adequately as the findings are recorded for posterity and peer review The computer issues a challenge, producing better records and thereby better conclusions with regard to management This results in the senior house officer being as good as, if not better than, the computer The results of the combination are fewer admissions, better communication of information to seniors, greater accuracy at the front door, fewer unnecessary laparotomies and more appropriate use of investigations.

Perhaps the strongest case for the use of the computer can be made on the grounds of audit of performance, creation of a patient record and the education of junior staff In our system this has been extended to include collection of investigation results and management decisions Herein lies an important power of modern technology which has led to the creation of management packages[3-5].

Non-operative management of splenic trauma in adults

Sir

The traditional treatment for splenic trauma has been splenectomy However, the observation that splenectomized children may develop overwhelming post-splenectomy infection has reversed the classical treatment of splenectomy for the management of splenic trauma. Conservative procedures such as splenorrhaphy, partial splenectomy and splenic autotransplantation have become common practice. The success of non-operative management in children with splenic trauma[1] and the observation that most adult patients have spontaneous cessation of bleeding before surgery, together with the ability to assess splenic damage by computerized tomography or ultrasonography induced us to attempt non-operative management in selected cases of adult splenic injury

We adopted a policy of restricting surgical intervention to patients where associated injuries were suspected Our non-operative method allowed blood transfusion to a maximum of 300 ml/h or a total of 3000 ml as long as vital signs were controlled. The patients were observed in the intensive care unit for the first 2 days. Bed rest was instituted for 7 days and vigorous exercise forbidden for 2 months Repeated computerized tomographic assessments were undertaken at 30-day intervals until complete resolution of the splenic damage was seen.

Using this method we have treated 15 consecutive patients with splenic rupture demonstrated clinically and by computerized tomography or ultrasonography. The mean age has been 35 years (8–62 years) with an average requirement for blood transfusion of 2500 ml. In one case operation was performed when an associated injury was suspected In every other case surgery was avoided and complete resolution of the splenic lesion was documented within a 2-month follow-up period.

These preliminary results have encouraged us to continue with this policy of non-operative management for isolated adult splenic trauma

Thermal gradients

Sir

We read with interest the recent paper by Rogers *et al* on thermal gradients in the anorectum and their contribution to continence (*Br J Surg* 1988, **75** 1083–5) and were pleased that this independent group should find a 'clear temperature gradient from the rectum to the anal verge'. As they rightly point out this is an essential prerequisite if temperature sensation contributes to sensory discrimination of rectal contents. Bearing in mind the differences in technique, their results are similar to our own previous study[1]

Their conclusion, however, reveals a serious shortfall in their understanding of sensory physiology They state that the difference in temperature between rectal contents and anal canal is below measured thermal thresholds in the anal canal and therefore that temperature sensation can play no part in continence.

Firstly, the sensation of rectal contents is not one of hot or cold but rather the feeling of a semi-solid/liquid (stool) or a gas (flatus). These experiences are 'blended sensations' (like the feeling of wetness on the skin) and are the result of a mixture of mechanical and thermal stimuli[2] Whether or not the temperature component alone needs to reach conscious thresholds is unknown but this is not a condition for temperature to have an influence (subthreshold or suprathreshold) in the perception of a 'blended' sensation

Secondly, even if conscious awareness was necessary, the thermal stimulation of the anal canal depends on factors such as surface area exposed to the stimulus, which can have a profound effect on measured thresholds[3] We used a 1-cm long thermode to study thermal sensitivity. Rogers *et al* stated that the healthy anal canal is 4 cm long[4] and sampling of rectal contents occurs at least as far as the mid-sphincter[1] This would result in 2 cm or more of mucosa being exposed to the stimulus, twice the length of the thermode The area exposed would be further increased by folds and corrugations of the anal mucosa.

Finally, the authors are concerned with the length of anal canal sensitive to thermal stimuli and yet in the few subjects studied they use a different stimulus, namely mucosal electrosensitivity to 'assess the length of sensitive mucosa'. At best this can only be described as illogical but it also assumes a direct correlation between thermal and mucosal electrostimulation which is not the case[5]. Furthermore, the lowermost rectum is also sensitive to thermal stimuli, albeit at higher thresholds than the anal canal[6].

Author's reply

Sir

We note the comments of Mr Miller *et al* on our paper (*Br J Surg* 1988, **75**. 1083–5) with interest Our paper is experimental evidence to support the original criticism[1] on theoretical grounds of the paper 'Anorectal temperature sensation. comparison of normal and incontinent patients'[2] which drew inappropriate conclusions about the role of temperature sensation in the anal canal and its possible relationship to the continence mechanism.

We were pleased to see that the points made in this original criticism were taken by the authors and incorporated into a subsequent paper[3] The median temperature differences they measured between the rectum and anal canal were between 3 and 4 times lower than the median thresholds necessary for conscious appreciation of temperature[2,4] This confirms our data and supports our conclusion that under normal physiological circumstances 'the conscious appreciation of temperature of faeces passing from the rectum to the anal canal is impossible during the anorectal "sampling reflex" '[5]

Their point about 'blended sensation' needs answering. There is scant evidence that subconscious appreciation of temperature change takes place in the anal canal or anywhere else Indeed the theory that the sensation of wetness includes the presence of mechanical and thermal stimuli is based on archaic observations on the effec of anterolateral chordotomy[6]. A recent review states 'Ordinarily, sensations of wetness include the presence of mechanical and thermal stimuli, but the necessary conditions have not been delineated, and the methods of testing patients have not been detailed appropriately'[7].

We would like to remind Mr Miller *et al* that all their data is related to conscious appreciation of temperature change in the anal canal, which is poor licence for the extrapolation of this data into the realms of 'subconscious' or 'blended sensations'. Acceptable as this may be for the discussion section of an MD or MS thesis we feel it is unacceptable in the presentation of a paper in a scientific journal

Our advice to anyone intending to set out to investigate the role of temperature sensation in the continence mechanism would be to measure and compare the anorectal temperature gradients and the thresholds of temperature sensation in each individual subject

Book reviews

Current Surgical Diagnosis and Treatment. 8th ed

L. W Way 182 × 260 mm Pp.1223 Illustrated 1988 Hemel Hempstead Prentice Hall £29 95.

The appearance of the eighth edition of this textbook of surgery testifies to its continued success and popularity although not, I suspect, on this side of the Atlantic. It remains in much the same form as previous editions, being the product of 82 authors primarily from the West Coast of America and under single editorship

After a general introduction and chapters relating to general medical and surgical topics important in the management of all patients, and including (perhaps with increasing relevance) 11 pages on 'legal medicine for the surgeon', the remainder of the book covers all organ systems and includes chapters on ENT, ophthalmology, orthopaedics, neurosurgery, cardiac surgery, plastic surgery, urology and paediatric surgery

Since the seventh edition there has been an updating of key references throughout the text (up to 1986) and several chapters have been either extensively rewritten, e.g surgical nutrition and head and neck tumours, or substantially revised

The editor is to be congratulated on achieving a uniform style throughout the text and adhering to the stated aim of 'serving as a ready source of information about diseases managed by surgeons and emphasizing quick recall of major diagnostic features and brief descriptions of disease processes Throughout the text the quality of line drawings is good, particularly where they remain simple The reproduction of radiographs is poor which perhaps explains some notable exclusions, e g not a single endoscopic retrograde cholangiopancreatogram in the chapter on the pancreas There is also considerable variety in illustrations of surgical technique. Based on the diagrams, I would be happy to remove an appendix but not atheroma from the carotid arterial system nor repair an aortic aneurysm.

These criticisms lead to my main concern and that is the perennial question 'to whom is the text directed'? The claim is that the intended audience comprise students, house officers and medical practitioners. As a text for the pre-fellowship trainee it is inadequate in detail in many areas and would, of necessity, have to be read in combination with other texts. The post-fellowship registrar seeking detailed information on a surgical disease or procedure would be disappointed although the up-to-date references might well point him in the correct direction However, I feel that this text can be recommended unreservedly to medical students in that it gives a good and comprehensive account of current surgical practice and is more than adequate for final examination. It remains to be seen whether a soft cover volume of over 1200 pages gains in popularity or, indeed, lasts the course

Growth Factors and Other Aspects of Wound Healing

A Barbul 156 × 235 mm Pp 329. Illustrated. 1988. New York· A R Liss $68.00.

This book presents the proceedings of the Second International Symposium on Tissue Repair held in Tarpon Springs, Florida in May 1987 I went to the first symposium in 1982, but I missed the second and was pleased therefore to review this book

It is a specialized book of great interest and is highly recommended to those involved in or interested in the biological aspects of wound healing, with particular emphasis on growth factors. All the well-known names in the field (mostly from the USA) are represented here, giving a complete and up-to-date account of recent advances There is a wealth of references after each chapter, albeit a little repetitive. It is a pity that the whole book was not typeset in the style of the introduction. I was not informed of its price, but I doubt whether it should grace the bookshelf of anyone other than the surgeon or biologist working in the field

Low Level Laser Therapy: A Practical Introduction

T Ohshiro and R. G Calderhead. 221 × 254 mm. Pp 129. Illustrated. 1988. Chichester. John Wiley & Sons. £30 50

Low level laser therapy (LLLT) is the Cinderella of medical laser applications The majority of laser treatments work by heat coagulation or vaporization of tissue with high energy laser beams; LLLT is said to exert its effect quite differently by mechanisms of biostimulation in tissue healing, nerve regeneration, and other areas which are difficult to assess in clinical practice. It is by no means clear how LLLT works in tissue healing or indeed, some may say, whether it even works at all.

This book represents a summary of LLLT work carried out, mainly in China and Japan, using helium–neon and GaAs lasers in the milliwatt range The physics of the lasers is discussed, followed by a number of examples of clinical applications of LLLT. Most of the work described involves wound healing and pain relief studies, and many of the case reports are well described and convincing in nature, particularly those involving hyperpigmentation of the skin The wound healing work is less convincing and some of the science in these areas is slightly patchy. There are a number of irritating errors, such as that where it is said that photons of different energies travel at different speeds (page 13). On page 55 it is said that human skin absorbs light maximally in the 500–650 nm range whereas absorption is higher at shorter wavelengths It is difficult to keep an open mind on LLLT; most readers of this book will already be convinced either that it works or that it does not, and there is very little in the text to confirm or refute either viewpoint

Clinical Progress in Nutritional Research

A Sitges Serra, A. Sitges Creus and S. Schwartz-Riera. 152 × 229 mm. Pp.281. 1988. Basel Karger. £53.20.

At the Ninth Congress of the European Society of Parenteral and Enteral Nutrition in Barcelona last year, 26 individuals from 13 countries were invited to present lectures on selected topics This paperback contains papers from these individuals and is a rather mixed production. Some of the papers consist of reviews and others of precise presentations of new work. The papers vary in length from two to 26 pages. Some are wideranging reviews referring to the knowledge gathered mainly by others and some reviews emphasize the authors' contributions Thus a paper by Singh and Chandra on 'The use of immunological indices for nutritional assessment and outcome' contains 30 references of which the first 15 refer to the authors' work in this field. The topics chosen are important for those undertaking research in this field and the book will also be useful as a reference for others who wish to extend their knowledge in specific areas of nutrition but, as the title implies, this is not a textbook of nutrition for clinicians.

Management of Gunshot Wounds

G J. Ordog 178 × 254 mm. Pp.461. Illustrated 1988. Amsterdam. Elsevier. $75 00

This book is unlikely to be widely read by surgeons on this side of the Atlantic where gunshot wounds are still comparatively rare in most clinical practices The multi-author text deals exhaustively with most aspects of gunshot wounds, but there is much overlap and repetition between the chapters. I found two chapters by the editor (ballistics and socioeconomics) particularly worthwhile

Most surgeons and trainees will benefit more from reading a standard trauma text (several have recently been published), that puts gunshot wounds in their true perspective as mechanisms of injury Those venturing to Belfast or the Bronx will find the book of more than passing interest but given the British antipathy for firearms there can be only a limited market for this book here

and **AMERICAN ASSOCIATION OF ENDOCRINE SURGEONS**

ORIGINAL COMMUNICATIONS

page 331 **Prospective comparison of gastric secretory function after gastrectomy with either Billroth II or Roux-en-Y anastomosis**
Paul N M. A Rieu, MD, Jan B. M J Jansen, MD, PhD, Harry J M. Joosten, MD, PhD, Izak Biemond, PhD, Sing H Yap, MD, PhD, *and* Cornelis B H. W. Lamers, MD, PhD, *Nijmegen and Leiden, The Netherlands*

337 **The dilemma of outcome assessment after operations for morbid obesity**
Robert E Brolin, MD, Hallis A Kenler, PhD, RD, Robert C Gorman, BS, *and* Ronald P Cody, PhD, *New Brunswick, N J*

347 **Is proximal pancreatoduodenectomy with pyloric preservation superior to total pancreatectomy?**
Molly K McAfee, MD, Jon A van Heerden, MB, FRCS(C), FACS, *and* Martin A Adson, MD, FACS, *Rochester, Minn*

352 **Anatomic correlates of bacterial cholangiovenous reflux**
Steven E Raper, MD, Mary E. Barker, PhD, Albert L Jones, MD, *and* Lawrence W Way, MD, *San Francisco, Calif*

360 **Risk factors of postoperative pulmonary complications after vascular surgery**
J Vodinh, MD, F Bonnet, MD, C Touboul, MD, J P Lefloch, MD, J. P Becquemin, MD, *and* A Harf, MD, *Creteil, France*

366 **The relationship of flow cytometric DNA analysis and clinicopathology in small-intestinal carcinoids**
Kenichi Tsushima, MD, David M Nagorney, MD, Louis H Weiland, MD, *and* Michael M. Lieber, MD, *Rochester, Minn*

374 **Late subjective and objective evaluations of antireflux surgery in patients with reflux esophagitis: Analysis of 215 patients**
Attila Csendes, MD, FACS, Italo Braghetto, MD, FACS, Owen Korn, MD, *and* Claudio Cortés, MD, *Santiago, Chile*

383 **Regional hepatic arterial infusion of degradable starch microspheres increases fluorodeoxyuridine (FUdR) tumor uptake**
Arleen K. Thom, MD, Elin R. Sigurdson, MD, PhD, Milad Bitar, PhD, *and* John M Daly, MD, *Philadelphia, Pa , and New York, N Y*

393 **Mechanical factors predisposing to intimal hyperplasia and medial thickening in autogenous vein grafts**
Philip B Dobrin, MD, PhD, Fred N Littooy, MD, *and* Eric D Endean, MD, *Hines and Maywood, Ill*

401 **Tc-NGA imaging in liver transplantation: Preliminary clinical experience**
E Steve Woodle, MD, Richard E Ward, MD, Robert C Stadalnik, MD, *and* David R Vera, PhD, *Sacramento, Calif*

408 **Choledochocele: Case report, literature review, and a proposed classification**
George E. Sarris, MD, *and* Donald Tsang, MD, *Stanford and Santa Clara, Calif.*

415 **Comparison of the effects of enteral feeding with continuous and intermittent parenteral nutrition on hepatic triglyceride secretion in human beings**
L Isabel-Martinez, FRACS, C Skinner, BSc, A. Parkin, DPHIL, *and* R. I Hall, FRCS, *Leeds, England*

421 **Effect of ibuprofen on the pulmonary and systemic response to repeated doses of endotoxin**
Robert H Demling, MD, Cheryl LaLonde, BS, *and* Mary E Pequet Goad, PhD, *Boston, Mass*

430 **Bilateral renal autotransplantation with pyelovesicostomy: A surgical treatment of refractory enteric hyperoxaluria**
Oscar Salvatierra, Jr , MD, Michael Longaker, MD, *and* Tim Crombleholme, MD, *San Francisco, Calif*

BRIEF CLINICAL REPORTS

436 **A forme fruste of von Hippel-Lindau disease: A combination of adrenal pheochromocytoma and ipsilateral renal cell carcinoma—A case report**
Joost M L M Horbach, MD, Stephan J. Brenninkmeyer, MD, Cornelis J H van de Velde, MD, *and* Arie C Nieuwenhuyzen Kruseman, MD, *Leiden, The Netherlands*

442 **Reconstruction of a functional hemidiaphragm with use of omentum and latissimus dorsi flaps**
Howard D Edington, MD, Steven Evans, MD, *and* William F Sindelar, MD, PhD, *Bethesda, Md*

446 **Transhepatic embolization of superior mesenteric varices in portal hypertension**
C Keith Ozaki, MD, Margaret Hansen, MD, *and* Saadoon Kadir, MD, *Durham, N.C*

449 **Axillary compression syndrome with neurapraxia due to operative positioning**
Raman N Nambisan, MD, *and* Constantine P Karakousis, MD, PhD, *Buffalo, N Y*

PIPRIL

INTRAMUSCULAR/INTRAVENOUS PIPERACILLIN

Still a key move in surgical infections

- Proven single agent activity[1-3]
- Broad spectrum cover, including anaerobes.[4] Active against *Strep. faecalis*[5] – unlike cephalosporins, aminoglycosides and metronidazole.
- Highly synergistic with aminoglycosides[6,7]
- Low potential for inducible resistance compared with 'third generation' cephalosporins[8,12]
- Effective concentrations in bile and peritoneal fluid[9,10]
- Well tolerated[11]

Prescribing Information. **Indications**: Pipril is a broad spectrum bactericidal penicillin for the treatment and peri-operative prophylaxis of systemic or local infections caused by sensitive organisms. **Dosage**: Adult patients with normal renal function should receive 4-8g daily in divided doses for mild or uncomplicated infections. In serious or life-threatening infections 12-16g daily in divided doses. For peri-operative prophylaxis 2g just prior to surgery followed by at least two doses of 2g at four or six hour intervals. Patients with renal insufficiency may need dosage reduction – see Data Sheet. Children 2 months to 12 years of age: 100-300 mg/kg daily in three to four divided doses. Neonates and infants under two months of age: 100-300 mg/kg daily in two equally divided doses. **Contra-indications**: Penicillin or severe cephalosporin hypersensitivity. **Precautions**: Safety for use in pregnant or lactating women has not yet been established. **Side effects**: Uncommon and typical of injectable penicillins. **Administration**: Pipril is presented as 1g or 2g vials, 4g infusion bottles and 4g infusion packs containing piperacillin as piperacillin sodium. See Data Sheet or package leaflet for full details of preparation and administration. **Product Licence No.** 0095/0073. **Basic NHS Price**: 1g vial £2.98, 2g vial £5.90, 4g infusion bottle £11.66. 4g infusion pack (4g bottle, 50 ml WFI plus needle) £12.43. Further information is available on request.

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer-Verlag 1981: 123–63.

NEW FROM BUTTERWORTHS

MANAGEMENT OF ABDOMINAL HERNIAS

H Brendan Devlin MA MD MCh (Dublin) FRCS(England) FRCS(Ireland) FACS
Consultant Surgeon, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

Management of Abdominal Hernias is the most comprehensive work to date on the subject. In this exhaustive volume the author discusses the historical background to hernia management and its influence on current practice.

The basic sciences and operative technique of hernia surgery are dealt with in practical terms and guidance on complications and postoperative care is supported by new data based on long term studies.

★ **the author is a leading authority on hernia management**

★ **extensively illustrated with high quality line drawings, half-tones and colour photographs.**

"This book is beautifully produced, clearly written and profusely illustrated, mainly by excellent line drawings. It would be of considerable value to the surgeon in training (who, in this country, is called upon to do the majority of this type of surgery) but it would also be read with interest by his Chief."

British Journal of Surgical Practice

"The anatomy of the abdominal wall is excellently set out and clearly described and I would recommend all surgeons in training, particularly at senior house officer level, to read it.

"This is a very readable and enjoyable book. It is not directed at any particular grade of surgeon but will inform and enlighten the majority of those who read it."

British Journal of Hospital Medicine

Concise contents: Preface · General introduction and history of hernia surgery · Essential anatomy of the abdominal wall · Epidemiology and aetiology of primary hernias in adults · Logistics and economics of hernia repair · Principles in hernia surgery · Anaesthesia · Complications of hernia in general · Groin hernias in babies and children · Umbilical hernia: operation in babies and children · Diagnosis of a lump in the groin in the adult · Inguinal hernia in adults · Femoral hernia · Extraperitoneal or preperitoneal repair of groin hernias using prosthetic reinforcement · Umbilical hernia in adults · Epigastric hernia · Obturator hernia, lumbar hernia, sciatic hernia, supravesical hernia · Spigelian hernia · Incisional hernia (excluding parastomal hernia) · Parastomal hernia · Complications of hernia repair · Epilogue and general conclusions · Biographical notes · References and further reading · Index

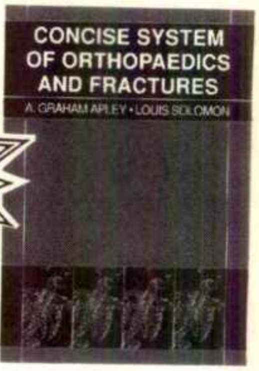
CONCISE SYSTEM OF ORTHOPAEDICS AND FRACTURES

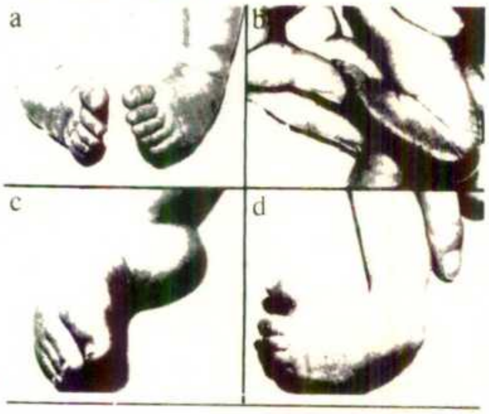
A. Graham Apley MB BS, FRCS, FRCSEd (Hon)
Consulting Orthopaedic Surgeon, St Thomas' Hospital, London, UK
Emeritus Consultant Orthopaedic Surgeon, The Rowley Bristow Orthopaedic Hospital, Pyrford, and St Peter's Hospital, Chertsey, Surrey
Editor, *Journal of Bone and Joint Surgery* (British Issue)

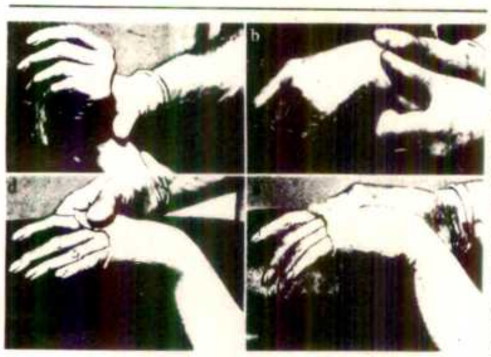
Louis Solomon MB ChB, MD, FRCS, FRCSEd
Professor of Orthopaedic Surgery, University of Bristol, UK
Formerly Professor of Orthopaedic Surgery, University of the Witwatersrand, Johannesburg

AVAILABLE ON INSPECTION



★ A shorter, revised version of the classic 'Apley's System' ★ Same systematic presentation – ideal for learning and revising ★ Nearly 500 illustrations, many presented as composites ★ Meets the needs of undergraduate and paramedical students





Apley's System of Orthopaedics and Fractures has for long been an established favourite. But it is a textbook designed primarily for postgraduates, and for many readers it is unnecessarily detailed. This new *Concise System* is a distillation of the larger book and will meet the needs of those looking for an introductory account of modern orthopaedics.

Systematic, balanced and easy to use, the *Concise System* is an outstanding textbook of orthopaedics for anyone seeking a brief account of this large subject. It is also a natural precursor to the more detailed coverage of the subject offered by its larger parent.

Contents * FOS MADE - IF NEEDED *

Part 1 General Orthopaedics
Diagnosis in orthopaedics · Infection · Rheumatic disorders · Gout and degenerative arthritis · Bone necrosis · Metabolic and endocrine disorders · Bone dysplasias · Tumours · Neuromuscular disorders · Peripheral nerve lesions · Orthopaedic operations

Part 2 Regional Orthopaedics
The shoulder · The elbow · The wrist · The hand · The neck · The back · The hip · The knee · The ankle and foot

Part 3 Fractures and Joint Injuries
Fracture pathology and diagnosis · Principles of fracture treatment · Complications of fractures · Stress fractures and pathological fractures · Injuries to joints · Injuries of the upper limb · Injuries of the spine, thorax and pelvis · Injuries of the lower limb

Advanced Surgical Techniques Course
26 – 28th June 1989

This is a 3 day course for specialists and trainees in surgery, with emphasis on recent developments, new techniques and specialised procedures in surgery.

There will be lectures and video presentations of surgical procedures. Speakers will include members of the Department of Surgery as well as eminent guest speakers.

Topics will include:

- *Ileal pouch construction*
- *Pancreatic resection*
- *Transhiatal oesophagectomy*
- *Myo-cutaneous flaps*
- *Post anal repair*
- *Intra/extra cranial grafts*
- *Urinary diversion techniques*
- *Sports injuries*
- *Partial hepatectomy*
- *Portal Shunts*
- *Liver transplantation*
- *Maxillo-facial surgery*
- *Lymphoedema surgery*
- *Intraluminal bypass procedure*
- *Endocrine surgery*
- *Bone tumour surgery*

Guess which prostate cancer treatment most patients would choose.

In a recent study[1], 57 prostate cancer patients were invited to participate in choosing their treatment. All were informed that the two treatments available, sub-capsular orchidectomy or 'Zoladex', were similar in efficacy and side effects. 49 of the patients (86%) opted for 'Zoladex'.

A recent trial[2] has established the equivalence of 'Zoladex' to orchidectomy.

Zoladex

goserelin

Effective therapy without surgery.

▼ **'ZOLADEX' PRESCRIBING NOTES.**

Use: Prostate cancer suitable for hormonal manipulation. **Presentation:** A sterile depot containing goserelin 3.6mg. **Dosage and administration:** One depot injected subcutaneously into the anterior abdominal wall every 28 days. **Precautions:** Care with patients at particular risk of developing ureteric obstruction or spinal cord compression. Consider initial use of an anti-androgen at the start of therapy. **Side effects:** Hot flushes, decrease in libido and occasional breast swelling and tenderness. Skin rashes (generally mild). Occasional mild bruising at injection site. Initial transient increase in serum testosterone may cause temporary increase in bone pain. **Product licence number:** 29/0198. **Basic NHS Price:** £114.00 per depot. 'Zoladex' is a trademark. Further information is available from: ICI Pharmaceuticals (UK), Southbank, Alderley Park, Macclesfield, Cheshire SK10 4TF.

Current indications for elective peptic ulcer surgery

Confusion exists over the role of elective surgery in the treatment of chronic duodenal ulcer. Many fewer operations are being performed and some have questioned whether there is any place for surgery for the uncomplicated ulcer.

Highly effective ulcer healing drugs are now available. Five H_2-receptor antagonists exist with more in the pipeline, De-Nol® (Brocades, West Byfleet, UK) and sucralfate are just as effective, and if any ulcer defies such an armamentarium, omeprazole will certainly heal it.

It is not enough merely to heal the ulcer; to alter the diathesis in any way, a permanent reduction in acid output is essential, though to what level is not accurately known. None of the available drugs alter the ulcer diathesis. Although a 2-month course of an H_2-receptor antagonist will heal 90 per cent of ulcers, most of these will recur within 1 year of stopping therapy and even on maintenance therapy the relapse rate is 2·5 per cent per month or 30 per cent per year. Within a day or so of stopping therapy gastric secretion returns to pretreatment levels.

In the 10 years that H_2-receptor antagonists have been available and prescribed in vast amounts there has been no reduction in ulcer mortality rate. Indeed in the last few years the number of deaths from peptic ulcer in England and Wales has increased and this is most marked in those over the age of 65 years[1]. The major complications of peptic ulceration, namely bleeding and perforation, now account for over 4500 deaths annually and in devising a strategy for treating peptic ulceration this consideration must be paramount. We can only reduce ulcer mortality by preventing these complications and if it is well recognized that they are most dangerous in the elderly. Indeed, 95 per cent of ulcer deaths occur in patients over the age of 55 years, the mean age in fatal cases being 71 years[1]. Clearly the widespread use of H_2-receptor antagonists is having no effect on ulcer mortality because most ulcers recur unless long term, often lifelong, full dose treatment is embarked upon. Some patients even develop bleeding or perforation while taking these drugs. A significant minority of ulcers occur in those without an established ulcer diathesis and without any previous dyspepsia; clearly nothing can be done, either medically or surgically, to prevent these asymptomatic ulcers from bleeding or perforating. Most patients who develop bleeding or perforation, however, have a history of a well established ulcer diathesis. It has been shown by Pulvertaft[2] that between the ages of 50 and 60 years, patients with chronic peptic ulceration run a 25 per cent risk of bleeding and a 10 per cent risk of perforation. The incidence of these complications increases over subsequent decades. The mortality rate after a bleed from a peptic ulcer remains today, as it has throughout this century, at 10 per cent, and the mortality rate for perforation is in excess of this, at approximately 12 per cent[3].

In elderly patients there is certainly no evidence that the widespread use of H_2-receptor antagonists is reducing mortality. The slight increase in mortality rate already referred to is, paradoxically, occurring at a time when the prevalence of peptic ulcer, the hospitalization of ulcer patients and the use of elective surgery have all declined dramatically.

The evidence does not exist to attribute this increased mortality to the reduction in the number of ulcer operations but this may be a factor. The other major potential factor, namely the use of non-steroidal anti-inflammatory drugs, has recently been called into question by an Australian case controlled study[4] which showed that neither aspirin nor other non-steroidal anti-inflammatory drugs were associated with increased case fatality rates from peptic ulceration. Although these drugs produce symptoms in patients with peptic ulceration, we do not know whether they cause ulcers; similarly we do not know whether H_2-receptor antagonists and other drugs, including prostaglandins, are protective and they probably are not. Vagotomy and other operations for peptic ulceration probably are to some extent protective, for though ulcers may recur after surgery these rarely bleed or perforate[5,6].

The risk of mortality after peptic ulcer surgery has fallen significantly in recent years, in particular with the introduction of highly selective vagotomy. The mortality rates for this operation and for anterior lesser curve seromyotomy with posterior truncal

0007–1323/89/050427–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

vagotomy are 0·3 per cent and 0·16 per cent respectively[7,8]. Recurrence rates between 14 and 18 years after highly selective vagotomy are worrying, they are reported to be 30 per cent in the longest term study. Even so, none of these recurrent ulcers has bled or perforated although 30 per cent of the patients had bled preoperatively[5]. Thus, recurrent ulcers after highly selective vagotomy, while highly undesirable, are rarely if ever life threatening.

If peptic ulcers are treated by the more radical operation of truncal vagotomy and antrectomy, the operative mortality rate and recurrent ulcer rate are both about 1 per cent. Small and his colleagues[6] carried out a long term study on 779 men with peptic ulcers treated surgically between 1947 and 1965 with a minimum follow-up of 15 years. Of the 360 deaths that had occurred none was related to peptic ulceration. Thus after peptic ulcer surgery people do not die from peptic ulcer complications.

In those patients with an established chronic ulcer diathesis, a condition developing in most before the age of 40 years[2], potentially fatal bleeding or perforation can therefore be prevented by elective peptic ulcer surgery which is extremely safe. On the other hand, up to the age of 50 years, peptic ulceration is not a life-threatening condition and no one should undergo surgery for this condition unless it can be shown to be beneficial, not only be relieving symptoms but also by reducing the risk of mortality. After all it was to prevent potentially fatal complications that ulcer surgery was initially promulgated before the First World War. The attitude towards elective ulcer surgery could be similar to that adopted in ulcerative colitis where operative treatment is used to prevent fatality from either perforation or malignancy. Here one operates on patients with an aggressive form of the disease which fails to respond to repeated courses of medical therapy and long term maintenance therapy and also on those with a history of 20 or more years of active disease. In this way, mortality from ulcerative colitis has been reduced and it is possible that surgery has the same potential in the ulcer diathesis.

To establish guidelines, one could recommend ulcer surgery for those who frequently relapse on maintenance therapy with H_2-receptor antagonists, relapse early after three or more 2-month courses of these drugs, and those who have relapsed after three or more courses of the drug at or about the age of 50 years. This last criterion would probably provide the largest group of patients who, on undergoing surgery at that age, would still benefit from the low mortality risk of pylorus preserving ulcer surgery, would have negligible morbidity in terms of dumping and diarrhoea, and would have an extremely low incidence of perforation or bleeding even if they developed a recurrent ulcer. The only alternative strategy over the age of 50 years would be life long continuous full dosage H_2-receptor antagonist therapy with the attendant problems of lack of compliance and ever-increasing cost. Employing this relatively conservative surgical strategy one could save large amounts of money in drug costs and transfusion requirements and significantly reduce the risk of mortality in the patient with an established ulcer diathesis.

Changing concepts in renovascular surgery

The kidney is an organ with exocrine as well as endocrine functions. The most well known endocrine function is renin production by the juxtaglomerular cells; renin is a proteolytic enzyme which interacts with angiotensinogen to form angiotensin I. A converting enzyme then produces the octapeptide angiotensin II, a potent vasopressor. A low blood pressure, such as that produced by a marked renal artery stenosis, causes increased renin secretion and thereby hypertension. When only one side is affected, nephrectomy can be used to treat the hypertension as first demonstrated by Howard *et al.* in 1954[1]. The sacrifice of renal parenchyma could, however, be accepted only if a good result could be predicted with regard to blood pressure control, and if the patient had a well functioning contralateral kidney.

With the advancement of reconstructive vascular surgery, nephrectomy soon became obsolete as a treatment for renovascular hypertension and was replaced by vascular reconstruction[2]. New, potent antihypertensive drugs have, however, offered strong competition to renovascular surgery. Today, this type of surgery must be effective, reliable and free from undue risks, in order to be an acceptable alternative in the treatment of renovascular hypertension.

There is, however, still a strong case for renovascular surgery, but the indication is now different. Antihypertensive medication, although valuable in the care of the hypertensive population, cannot prevent the progress of the arteriosclerotic disease. The decreasing renal blood flow, caused by progressive stenosis, impairs exocrine kidney function. The end point of this process is thrombotic occlusion of the stenotic renal artery. The main current indication for renovascular surgery, at least in arteriosclerotic disease, is therefore not to decrease blood pressure but to preserve and restore renal function.

The risk of an arteriosclerotic renal artery stenosis progressing to occlusion is quite high in contrast to that of stenosis caused by fibrous dysplasia. In various reports, between 10 and 17 per cent of arteriosclerotic renal artery stenoses have been found to occlude within 2–3 years[3,4,5]. It has also been reported that about 40 per cent of patients with one-sided arteriosclerotic renal artery stenosis develop contralateral stenosis within 52 months[4].

Can we predict which renal arteries with arteriosclerotic stenosis will occlude? We have recently studied 24 patients, whose stenotic arteries have occluded during work-up, or during efforts to treat the patients conservatively[6] (H. Weibull *et al.*, unpublished results). These were compared with a series of patients whose stenotic arteries remained patent for a similar length of time.

Although it is difficult to predict occlusion in individual patients, there are clear differences between the two groups: the group that occluded were significantly older (median age 64 *versus* 55 years), had narrower stenosis (1·0 *versus* 1·5 mm), and had more advanced generalized arteriosclerosis, including contralateral renal artery stenosis (50 *versus* 9 per cent) and ischaemic heart disease (90 *versus* 70 per cent). These patients obviously also represent a high-risk group from a surgical point of view.

Can we diagnose the occlusion once it occurs? It is well known that acute occlusion of a non-stenotic artery, due to embolus or trauma, often but not always causes flank pain as a sign of partial or complete renal infarction[6]. Urine output may decrease and serum creatinine rise, but this is not marked if the contralateral kidney is functioning well. Occlusion as the end result of renal artery stenosis is more difficult to detect. In our series of 24 patients, where we had a relatively limited period during which a stenotic renal artery is known to have occluded, all patients had indeed some signs or symptoms, although they were usually vague and therefore overlooked. The most important sign was a slight but significant rise in serum creatinine (in 23 patients), indicating impaired kidney function also on the contralateral side. Furthermore, a decrease in the length of the kidney was a regular finding. Flank pain was found in five of the 24 patients, shortness of breath in four, malaise in four, fatigue in three and headache in two.

In the light of this knowledge: which patients should be treated actively, and what type of active treatment should we choose, surgical reconstruction or percutaneous transluminal angioplasty?

It is technically easier, and the results are better, when a stenotic but patent renal artery is reconstructed as opposed to an occluded one. This should favour an active, prophylactic attitude being adopted towards the group of patients who are at high risk of renal artery occlusion. They also belong, however, to a high-risk group from

0007–1323/89/050429–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

a surgical point of view, and many factors have to be considered before we advise these patients to undergo major surgery. Knowledge of the high risk of occlusion in certain types of patients is, however, important when discussing the indications to operate on patients with renal artery stenosis.

The management of the patient with an occluded renal artery is no less difficult. Occlusion of a non-stenotic renal artery, due to embolus or trauma, often results in a renal infarct. In order to save such a kidney it is necessary to intervene within 24 h by embolectomy, induced thrombolysis or vascular reconstruction[7]. When a previously stenotic renal artery occludes, the situation is quite different. Collaterals have usually developed and preserve kidney viability. As the symptoms are vague, the diagnosis is often overlooked or made, often accidentally, a long time after the occlusion. In our handling of these patients we have several options[8]. If there is a well functioning kidney on the contralateral side, we may choose to do nothing, or, if there is a reasonably severe hypertension, we may remove the kidney with the occluded artery. If there are any problems with the kidney or renal artery on the contralateral side, we should, however, make every effort to revascularize the kidney on the occluded side. Unfortunately, there are no reliable ways to predict success in these cases[5,9,10]. Unfavourable factors are: small size of the kidney (less than about 9 cm in length), poor visualization of the kidney in the nephrographic phase, no excretion of contrast medium, and no filling of the renal artery distal to the occlusion. A long interval between occlusion and revascularization probably also decreases the chance for success, but this time is often unknown. Preoperative renal biopsy does not seem to be of any help. Although the risk of failure of a reconstruction is higher in occluded cases than stenotic ones, the success is sometimes remarkable, with retrieval of function that has been lost for several weeks. This is important for patients in an age group where chronic dialysis is not an attractive alternative[9].

Regarding the choice of method for revascularization, reconstructive vascular surgery or percutaneous transluminal angioplasty (PTA), there is a wide difference of opinion. Satisfactory results of PTA have been reported in patients with fibromuscular disease[11], but the results have been more disappointing in patients with arteriosclerotic lesions, especially those involving the aortic ostium of the renal artery[12]. In these patients there is a high risk of initial failure, and of early recurrence of the stenosis. We have been particularly disappointed with PTA in patients with a severely ischaemic kidney and impaired excretory function. Even after successful dilatation, there has sometimes been permanent damage to the renal parenchyma, possibly caused by injection of contrast medium in the ischaemic kidney during the procedure[13]. A prospective, randomized study, comparing reconstructive surgery and PTA, is now being performed at our institution and will, we hope, throw some light on this difficult problem.

A total of 1355 patients underwent internal sphincterotomy for chronic fissure in ano *between 1980 and 1985. Surgical data were obtained for 1102 patients, and 829 patients responded to a questionnaire. Of the 1057 for whom the time of healing was recorded, 1033 (97·7 per cent) healed by a mean time of 5·6 weeks. No significant differences in satisfaction with the outcome or in deficits in continence were noted between groups undergoing lateral, bilateral or posterior midline sphincterotomy. Excision of the fissure was found to be unnecessary. According to responses on the questionnaires, deficits in continence ranging from 'sometimes' to 'frequently' included lack of control of flatus (35·1 per cent), soiling of underclothing (22·0 per cent) and accidental bowel movements (5·3 per cent). A significantly higher proportion of patients who had accidental bowel movements were aged over 40 years.*

Keywords: Internal sphincterotomy, anal fissure, continence

The surgical treatment of chronic fissure *in ano* has evolved, in accordance with the thesis of hypertonicity of the internal sphincter, to procedures that temporarily or permanently decrease or eliminate the spasm in the internal sphincter. Although sphincter stretch accomplishes healing of the fissure[1,2], its simplicity is marred by the consequences of uncontrolled sphincter dilatation and ecchymoses with resultant fibrosis. The procedure has been modified from the original uncontrolled sphincter stretch under general anaesthesia to a controlled insertion of four fingers for a period of 4 min. The high incidence of disturbance of anal continence and the recurrence rate of 16 per cent[3] have resulted in the unpopularity of this procedure.

Recent manometric studies of the anal sphincter in normal individuals and fissure patients demonstrate an underlying sphincter anomaly that results in the occurrence and persistence of anal fissure. Nothmann and Schuster[4] recorded increased resting pressure of the anal sphincter in patients with anal fissure. They found that the abrupt relaxation of the internal sphincter in response to rectal distension does not gradually diminish with a return to base-line pressure as it normally should. Instead, the period of relaxation is followed by a significant and prolonged contraction of the anal sphincter to higher than initial base-line levels. This characteristic 'overshoot' response was seen in 90 per cent of the fissure patients compared with 26 per cent of normal subjects. The overshoot phenomenon disappears temporarily after sphincter stretch treatment of fissure. The normal resting pressure is evidently maintained longer after surgical sphincterotomy.

Eisenhammer[5,6] described lateral internal sphincterotomy for the treatment of anal fissure. Although Notaras[7] is generally credited with having first performed subcutaneous lateral sphincterotomy, Ribeiro[8] described the technique in 112 patients in 1960. Controversy still exists regarding minor variations in technique and differences in effectiveness between posterior midline, unilateral, and bilateral sphincterotomy; subcutaneous *versus* open sphincterotomy; excision, 'landscaping' (excision of proximal papilla and distal anal tag without excising the fissure), or fissurectomy; and local, general or regional anaesthesia.

A total of 1355 patients with chronic fissure *in ano* were treated by sphincterotomy at HealthEast Teaching Hospitals over a 5-year period. The data were analysed to determine the extent to which sphincterotomy resulted in long-term defects in continence, and whether sequelae differed according to the type of sphincterotomy performed.

Patients and methods

Questionnaires were mailed to 1355 patients who had undergone surgery for chronic fissure *in ano* between 1980 and 1985 Chronic fissure *in ano* was defined by a history of more than 4 weeks of symptoms and the appearance of chronicity with lack of oedema, evidence of scar tissue at the edges of the raw area, and the visibility of internal sphincter fibres in the base of the ulcer.

Responses were received from 829 patients (61·2 per cent), and surgical data were obtained from co-operating physicians for 1102 (81·3 per cent) of the total population. Matching surveys with respective surgery data yielded a common subset of 717 subjects (52·9 per cent). In the larger group there were 642 female and 460 male patients ranging in age from 14 to 89 years (mean 42 8 years). Bleeding (72·6 per cent), itching (34·9 per cent), burning (33·0 per cent), protrusion (24·3 per cent) and pain (23·5 per cent) were the most common symptoms Of the total group, 16·4 per cent had undergone previous anorectal surgery, and 3 1 per cent had had previous surgery for fissure *in ano* Inflammatory bowel disease was identified in seven patients and diabetes in 18.

The distribution of gender and location of the fissure as assessed from surgical data is shown in *Table 1*. In the records of 25 patients the location of the fissure was not noted. As expected, anterior fissures were more frequent in female patients (18·3 per cent). Severe stenosis was present in 7 1 per cent of the patients, moderate stenosis in 16·9 per cent, and minimal stenosis in 76·0 per cent The criteria for degree of stenoses were subjective, according to the surgeon's evaluation, but inability to insert even the smallest dimension Hill–Ferguson retractor at the time of surgery (following infiltration of local anaesthesia) was the objective criterion for severe stenosis.

Associated haemorrhoidal disease was present in the majority of the patients (93·4 per cent). Of the 1077 patients with full surgical data, 347 (32·2 per cent) had a distal sentinel tag, 210 (19·5 per cent) had proximal hypertrophic papilla, and 107 (9·9 per cent) had bridged-over skin forming a 'fistula'.

The type of sphincterotomy performed is shown in *Table 2*. In 126 of the 1102 cases with surgical data the type of sphincterotomy was not

Table 1 *Location of fissure*

Location	Total	Male	Female
Anterior	271	74 (6·9)	197 (18 3)

defined. The majority of the patients (49·3 per cent) had bilateral internal sphincterotomy, 62·6 per cent of which were performed by open technique. The associated haemorrhoidal pathology was excised and the wounds were closed completely with 5·0 polyglycolic acid suture. The operation was performed with local anaesthesia in the jack-knife position, as described previously by the authors[9]. The type of sphincterotomy (and the degree) was performed according to the personal preference of each of the five operating surgeons. It was the generally accepted practice that a large Hill–Ferguson retractor could be inserted comfortably into the anal canal at the conclusion of the procedure. Although subcutaneous sphincterotomy has been advocated as a therapeutic alternative[10], we did not employ this technique as a primary method of treatment.

A majority of the patients were discharged from the hospital after an overnight stay. An early bowel movement was encouraged and induced with four tablets of Dulcolax* (Boehringer–Ingelheim Ltd., Ridgefield, Connecticut, USA) administered the evening of surgery.

Total	503	9	512	

*One patient with unsatisfactory healing had missing excision data, †$P=0\cdot79$, ‡$P=0\cdot24$ (closed *versus* trimmed)

Results

Healing time was noted in the case notes of 1057 patients: 1033 fissures (97·7 per cent) healed satisfactorily taking a mean time of 5·6 weeks. Of the 24 patients with unsatisfactory healing, three underwent reoperation after 12, 14 and 50 weeks: two had deeper sphincterotomies, and one had a posterior sliding graft[11]. Fifteen patients with delayed healing who chose not to have further surgery subsequently healed over a period of 26–78 weeks. Six patients were lost to follow-up.

χ^2 analyses showed that there were no significant differences in healing between the various types of sphincterotomies performed ($\chi^2=2\cdot74$, $P=0\cdot50$) or between fissures that were excised or not excised ($\chi^2=0\cdot55$, $P=0\cdot76$; *Table 3*). Of the 536 fissures that were excised, χ^2 analysis showed no difference in healing between excision of the fissure *versus* 'trimming' without fissurectomy (χ^2 (with Yates' correction)$=0\cdot46$, $P=0\cdot79$). Of the 512 patients whose fissures were not excised, there was no difference in healing between those trimmed or not trimmed ($\chi^2=0\cdot32$, $P=0\cdot24$). Excision data were missing from 54 records.

Continence

Deficits in continence according to type of sphincterotomy performed are shown in *Table 4*. χ^2 analyses showed no differences between sphincterotomies in terms of lack of control of gas, soiling of underclothing, or accidental bowel movements. The responses on 829 questionnaires involving defects in continence and gender were analysed (*Table 5*). Overall, 35·1 per cent of the patients complained of lack of control of gas ranging from 'sometimes' to 'frequently'. No difference in control of gas was experienced according to gender. Twenty-two per cent of the patients admitted to soiling of underclothing 'sometimes' to 'frequently'. Men reported a significantly higher incidence of soiling (32·7 per cent) then did women (14·0 per cent). An alarming 5·3 per cent of the patients complained of accidental bowel movements for which 4·0 per cent regularly wore absorbent pads. However, only 56 patients (7·8 per cent) responded that they were extremely dissatisfied or not very satisfied with the outcome of their surgery (*Table 6*). Of the 21 male patients who complained of accidental bowel movements 15 were older than 40 years, of the 23 female patients with this problem, 17 were also in that age category. χ^2 analysis showed that there was a significantly higher proportion of patients aged over 40 years who were suffering from accidental bowel movements ($\chi^2=5\cdot2$, $P<0\cdot02$).

Total	829	352	477

Values in parentheses are percentages

As many as 42 per cent of the respondents (50 per cent of men and 36 per cent of women) admitted to their bowels being 'loose', ranging from 'sometimes' to 'frequently' It was suggested that poor diet, beer drinking habits and history of loose bowels may very well forewarn against a poor outcome of sphincterotomy for treatment of fissure *in ano*.

Discussion

If it is the assumption that internal sphincterotomy is the procedure of choice in the management of chronic fissure *in ano*, the debate should logically address not only the result in terms of healing of the fissure but also the overall impairment of physiology and its social consequences. Varying degrees of incontinence following lateral internal sphincterotomy have been reported in the literature. Vafai and Mann[12] reported an incidence of 1 per cent permanent partial incontinence for faeces after closed lateral internal sphincterotomy under local anaesthesia in 702 patients. Bailey *et al.*[13] reported an incidence of incontinence of 1 per cent for gas and 1·2 per cent for faeces in an evaluation of 418 patients who had lateral internal sphincterotomy performed. Six of the 99 patients interviewed by Hoffmann and Goligher[3] were unable to control flatus satisfactorily, and one had additional occasional incontinence for faeces. Walker *et al.*[14] conducted a long-term follow-up (mean 4·3 years) on 100 patients who had undergone internal sphincterotomy for anal fissure and stenosis. Fifteen per cent showed minor defects in continence, but none had faecal soiling severe enough to require a pad. The reported incidence of incontinence in other reports[15–17] ranges from 3 to 50 per cent.

This survey and others have reported a disturbingly high incidence of permanent incontinence. Could the ill effects be lessened or eliminated by attention to operative technique? Eisenhammer[6] warned particularly against division of more than the lower half of the internal sphincter, but Bennett and Goligher[17] found that frequency of such disorders was little affected by extent of the sphincterotomy. Bennett and Duthie[18] thought that the relatively insensitive furrow in the posterior midline following sphincerotomy allowed faecal matter to escape surreptitiously from the rectum to the exterior without evoking the normal sphincter response Unfortunately, a high incidence of defect in continence also results following bilateral internal sphincterotomy. The pelvic floor physiology laboratory at our institution is now studying the pre- and postoperative functional abnormalities of the internal sphincter following surgical division of a large bulk of the internal sphincters. Central to the unresolved questions are the issues discussed below.

Does the fissure have to be excised?

The results of the present study suggest that it is not necessary to excise the fissure. It might even be suggested that excision of the fissure with creation of a fresh surgical defect is undesirable. We found there to be no difference in healing between the patients with excised and non-excised fissures. Indeed, of the 288 patients for whom the fissure was neither excised nor trimmed, only six had prolonged healing (*Table 3*).

Table 6 *Satisfaction with the outcome of surgery by type of sphincterotomy*

	Type of sphincterotomy				
	Left lateral	Right lateral	Bilateral	Posterior	Total
Extremely/very satisfied	134	56	256	44	490
Satisfied	65	15	76	12	168
Extremely/very dissatisfied	18	4	30	4	56
Total	217	75*	362†	60	714

*missing record; †missing records; $\chi^2=8{\cdot}68$, $P=0{\cdot}19$ (four types of sphincterotomy and three levels of satisfaction/dissatisfaction compared)

Unilateral/bilateral sphincterotomy versus *posterior midline sphincterotomy*

Posterior sphincterotomies were performed in 60 patients from the subset of 717 whose operative reports specifically described nature of the procedure and who responded to the questionnaire (*Table 4*). There were no statistically significant differences in continence or ultimate outcome among any of the sphincterotomy types. Bilateral sphincterotomy was performed on approximately 50 per cent of the patients.

Subcutaneous versus *open sphincterotomy*

In this series, subcutaneous sphincterotomy was performed on one side only in conjunction with open sphincterotomy on the other. Therefore no valid conclusions can be drawn. Reports in the literature attest to the effectiveness of subcutaneous sphincterotomy[10]. It does not eliminate, however, the associated pathology present in the majority of patients presenting with fissure *in ano*.

Local versus *general anaesthesia*

Although there are studies claiming the superiority of general anaesthesia for the performance of subcutaneous sphincterotomy[19], in our experience with a vast number of anorectal procedures, adequate procedure may be performed with local anaesthesia, particularly if the jack-knife position is preferred.

Internal sphincterotomy in the management of fissure *in ano* is clearly safe and effective, but is often associated with disturbing consequences of deficit of continence. Particular caution in the depth and the length of sphincterotomy performed, especially in patients over 40 years of age, may be necessary. Perhaps a routine preoperative manometric study could accurately determine the extent of sphincterotomy to be performed.

Announcement

Association of Surgeons in Training

Membership of the Association is open to all senior registrars holding accredited posts in general surgery, urology, plastic surgery, neurosurgery, orthopaedics, cardiothoracic surgery and paediatric surgery. Registrars in the above specialties who are 2 years post-fellowship may also apply. The Association represents the views of members on all matters relevant to surgical training besides holding scientific and social meetings. If you are not a member please contact the Secretary, Andrew McIrvine, 35, Elsie Road, Dulwich, London SE22 8DX, for details of membership, local representatives and forthcoming meetings. The next AGM will be held in Cardiff from 21–23 September 1989.

Obstacles to organ donation

R. E. Wakeford and R. Stepney*

*Cambridge University School of Clinical Medicine, Addenbrooke's Hospital, and *14 Edward Street, Cambridge, UK*

Correspondence to:
Mr R. E. Wakeford, Office of the Regius Professor of Physic, Cambridge University School of Clinical Medicine, Addenbrooke's Hospital, Cambridge CB2 2QQ, UK

Attitudes towards transplantation were investigated in national surveys of the general public (n=*1471*)*, the medical profession* (n=*590*) *and key clinical staff in units referring potential organ donors* (n=*380*)*. A clear majority of doctors would like to see more transplants. Only 16 per cent of doctors opposed them on cost grounds, and a 50 per cent 5-year survival rate is seen as more than adequate clinical justification. However, doctors are less supportive of liver and heart grafts than of kidney and cornea grafts. Few lay people would refuse donation of specific organs, but 30 per cent worry that doctors might be pressured into removal of organs when they are not sure the patient is dead. Religious or moral objection is rare. Intensive care unit staff felt the most important factor restricting organ harvest in their own units was dislike of adding to relatives' distress, followed by lack of training in approaching relatives and adverse media publicity. Only 11 per cent thought reservations on brain stem death a likely or possible influence. Enhanced public awareness of the need for transplants was seen as the most important means of increasing organ harvest. Required request would be controversial and perhaps impossible to implement. We conclude that the time, effort and expense involved in potential organ donation do not play a substantial part in limiting referral. Neither do reservations about brain stem death. Increased training of staff* (*both in communication skills and in the professional responsibility to encourage donation*) *and greater public awareness are seen as the twin foundations of a realistic approach to enhancing referral.*

Keywords: Organ procurement, transplantation, attitude of health personnel, public opinion, medical education

An estimated 3500 patients are awaiting renal transplants, and waiting lists for heart and liver transplants and corneal grafts have doubled in the past 2 years[1]. Particularly in the case of renal transplants, it is widely accepted that these delays are due to a shortage of organs (rather than to limited facilities) and that much of the shortfall in organs could be met if more medically eligible brain stem dead patients were referred as potential organ donors[1–5].

In 1981, it was calculated that 4000 cases of brain stem death occurred each year in the UK, yet there were only 1000 renal transplants[4]. A more recent 3-year study[2] of brain stem dead patients in Nottingham showed that in the area covered by the transplant unit 50 kidneys per 10^6 population per year were suitable for transplantation, but that only half of the patients were being referred for kidney retrieval. Ninety of the 105 patients diagnosed as brain stem dead during the study were judged suitable for liver donation and 71 for heart donation, yet only five livers and 14 hearts were recovered. In 6 months of prospective study, organs from six brain stem dead donors were used, while organs from nine potential donors were not; in two cases relatives were not approached, while in seven cases relatives were approached but refused consent. Although medical staff were more likely to broach the subject of organ donation than a decade earlier[3], lack of policy on who should approach relatives was thought to be implicated in this high rate of loss.

Given wide variations in organ procurement from hospitals with similar patient populations, and from the same hospital in different years as staff change, Jennett and Hessett[4] argued that doctors' reluctance to initiate donation, rather than the refusal of relatives, was the important factor underlying poor rates of organ harvest

The Conference of Medical Royal Colleges and their Faculties has recently reported on the supply of donor organs for transplantation[1]. The report suggested a number of possible reasons for the shortfall in organs: lack of medical experience and knowledge, doubts about the success of transplants and the brain stem death criteria, demand for intensive care unit (ICU) beds, time constraints (including in theatre), cost, and medicolegal constraints During the preparation of the report, a questionnaire was sent to all ICUs. However, the survey had to be conducted quickly, so that only 108 replies were received (about a 37 per cent response rate), and no data derived from the questionnaire were presented

We undertook a large-scale survey of staff working in intensive care and related units. Its aim was to identify the obstacles to increased organ harvest, as seen by those most directly involved in referring potential donors, and to obtain their views on suggested changes in the way consent for organ donation is obtained. However, it is clear that the availability of organs for transplantation is affected by the views of the wider medical community and also, crucially, by public attitudes. The questionnaire study of intensive care staff was therefore complemented by surveys of public and professional opinion. All three surveys were conducted in November and December 1987.

Methods

The surveys

The general public survey Questions relating to transplantation were included in an 'omnibus' public opinion poll (conducted by Research International Medical Research/Marplan). In all, 1471 people, a representative national sample of the adult population in

0007–1323/89/050435–05$3.00 © 1989 Butterworth & Co (Publishers) Ltd

the UK, were interviewed. Respondents were first asked whether their general practitioner (GP) had raised the matter of organ donation with them, and if they would like him/her to do so Other questions concerned: attitudes towards transplantation generally and to specific organ transplants, beliefs about doctors' ability to diagnose death accurately (and their response in this situation to medical colleagues pressurizing them to make this diagnosis), and possible changes to the rules surrounding organ donation (the introduction of 'opt in', 'opt out' or 'required request')

The medical profession survey. Two random samples of doctors were drawn from the files of the mailing agency used by the Department of Health to contact all doctors. The first consisted of 250 GP principals, and the second sample consisted of 750 hospital doctors in the National Health Service (NHS) at registrar grade and above The sample of hospital doctors was larger to allow breakdown by general specialty.

These 1000 doctors were sent an explanatory letter accompanying a nine-item questionnaire covering attitudes towards transplantation in general and towards the transplantation of specific organs The statements with which respondents were asked to agree or disagree (anonymously) covered potential religious/moral, clinical and financial objections Responses were analysed for the group as a whole and (using the χ^2 test) by gender, age and specialty. We report differences significant at $P<0.02$

Medical and nursing intensive care staff survey. After discussions with three regional transplant co-ordinators, pilot telephone interviews were conducted with ten senior medical and nursing staff from five ICUs judged representative of different types of hospital The semistructured interviews explored attitudes towards referral of potential organ donors and possible obstacles to increasing the yield of organs The information obtained was used in designing an anonymous postal questionnaire

Two questionnaires were sent to each general, neurosurgical and paediatric ICU listed in the 1987 Directory of Emergency and Special Care Units[6] Combined ICU and coronary care units were sent questionnaires if their specified interests included head injury, trauma, neurosurgery or 'general'. A total of 590 questionnaires were sent, addressed personally to the senior consultant and the senior nurse in each unit, using names listed in the directory. Questionnaires were not sent to burns or neonatal ICUs, units concerned purely with coronary or postsurgical care, or to accident and emergency departments Respondents gave information on the type of hospital and unit in which they worked

Data have been analysed for the survey population as a whole, and (using the χ^2 test) by staff category (doctor or nurse), type of hospital and type of ICU. We report differences significant at $P<0.02$.

Results

Public attitudes

Only 2 per cent of respondents said that their GP had talked to them about the possibility of donating their organs for transplantation. Twenty-five per cent said that they would like their GP to do so and would value his advice, and a further 27 per cent said they would be prepared for the GP to discuss the matter, although they were not sure it would change anything. Thirty-five per cent regarded the matter as none of the GP's business, and 13 per cent could not answer.

On the question of establishing death after a serious accident, 53 per cent of respondents said they would trust doctors completely to be sure a person was really dead, 28 per cent would trust them but had 'a tiny doubt', 12 per cent were not sure and had major worries, 2 per cent would not trust doctors at all, and 4 per cent did not know. Responses to this question were virtually unchanged when the item was rephrased to ask what people would feel if they themselves had had the accident.

Sixty-three per cent of the sample were sure that doctors would never give permission for the removal of organs unless they were certain the patient was dead, even when under pressure from transplant doctors who needed the organs urgently. However, 30 per cent worried that doctors might sometimes be pressurized in that way Seven per cent answered 'don't know'.

Only 5 per cent of those interviewed said they had any moral or religious objection to the transplantation of organs from a dead person to a live one. Seventy-eight per cent said they would certainly agree to a heart transplant that might save the life of their child; only 5–6 per cent said they would themselves refuse the transplant of a heart, liver, kidney, lung, pancreas or cornea. When it came to having organs taken from them, rates of refusal were marginally greater: 9 per cent for the heart; 7 per cent each for the kidneys, liver and pancreas, and 11 per cent for the cornea.

Twenty-two per cent of the sample said they had a donor card, but only 14 per cent had it with them at the time of the interview. Asked why people did not carry donor cards, 44 per cent suggested it was because they had not thought about donating organs, 24 per cent that they could probably not be bothered, 15 per cent that people might worry about not being completely dead when organs were removed, 9 per cent that they might have moral or religious objections, and 8 per cent because people might think it was tempting fate.

The respondents were asked three questions relating to possible changes in the rules regarding organ donation, aimed at increasing the supply for transplantation. One suggestion dealt with an opt-out system (unless you registered an objection on a central computer, doctors could assume that when you die your organs can be removed, subject to your family's wishes); another involved the opt-in system (people who want to donate their organs should notify a central National Health Service office which would hold their names on a computer, and then they would not need to carry a donor card), a third suggestion involved required request (doctors should be required to ask the relatives of a newly dead patient whether his or her organs might be used for transplantation). Responses are shown in *Table 1*.

Finally, the respondents were asked about the status of a patient's dying request that his or her organs be used, even though relatives disapproved. Seventy-one per cent thought the last request should always be followed, but 17 per cent that it should not be followed if to do so would upset the relatives.

The medical profession

Eighteen questionnaires were returned as undeliverable, and 590 replies were received (60 per cent of those delivered). The response rate for GPs (61 per cent) was similar to that for hospital doctors (59 per cent).

Five per cent of respondents were aged under 30 years, 33 per cent were 30–39 years old, 32 per cent were 40–49 years old, 21 per cent were 50–59 years old, and 9 per cent were aged over 60 years Eighty-six per cent of respondents were men, and 14 per cent were women GPs accounted for 26 per cent of responses; 25 per cent were from doctors in hospital general medicine or medical specialties, 31 per cent from those in surgery or surgical specialties, 9 per cent from doctors working in laboratory or diagnostic specialties, and 7 per cent from those working in other categories.

The overall figures presented are arithmetic means of all responses. GPs, who represent half of all doctors, were deliberately under-represented in the sample drawn. However,

Table 1 *Public attitudes towards suggested changes in rules regarding organ donation*

	Respondents' views of the suggested changes ($n=1471$)				
Suggestion	Very good	Fairly good	Don't know	Fairly bad	Very bad

Lack of unit policies etc. regarding brain stem death and subsequent referral	21 (6)	36 (10)	314 (85)
General distaste on behalf of unit member(s) for the procedures involved in organ harvesting	19 (5)	78 (21)	277 (74)

From six to nine subjects did not respond to each item; values in parentheses are the percentages of those responding to each factor

crudely weighted means do not differ substantially from these means.

Overall figures are shown in *Table 2*. Medical opinion was overwhelmingly in favour of organ transplantation in general. Very few respondents had moral or religious objections. A majority of respondents agreed or tended to agree that transplantation was such an important topic it should be given considerable prominence in undergraduate medical teaching. Fifty per cent 5-year survival is clearly regarded as adequate justification for these views. On balance, doctors strongly supported transplantation on cost grounds.

When asked about specific organs, respondents' support for kidney and corneal transplants was clearly greater than for transplantation of the liver and heart. However, even with liver and heart transplants, the number of respondents voicing full or qualified disagreement was small.

Age was significantly related to attitude to the statement about survival ($P < 0.005$). There was an increase from 7 per cent among those aged under 40 years to 22 per cent in those aged over 60 years in the proportion of respondents agreeing or tending to agree that transplantation would not be justified by 5-year survival rates of 50 per cent. Older practitioners were also more inclined than younger ones to disapprove of heart transplants ($P < 0.005$). Twenty-two per cent of those aged over 60 years fully disagreed or tended to disagree with them, compared with 10 per cent of respondents under 30 years of age and 11 per cent of those aged 30–39 years. There were no significant differences by specialty or gender.

Intensive care staff

Two questionnaires were returned undelivered. Responses were received from 380 people – a 65 per cent response rate Twenty-one per cent were from major teaching hospitals, 27 per cent were from district general hospitals with regional specialties, 46 per cent were from district general hospitals without regional specialties, and 5 per cent were from other types of hospital. Fifty-seven per cent of respondents worked in general ICUs, 25 per cent in mixed ICU and coronary care units, 5 per cent in neurosurgical units, 6 per cent in paediatric ICUs and 7 per cent in other types of unit.

To obtain an early indication of likely responses, questionnaires were sent out in two waves: first to an initial sample of 120 ICUs drawn randomly from the directory and then, 14 days later, to the remainder. Owing to a printing error on the first batch of questionnaires, these respondents were not asked to specify whether they were doctors or nurses. However, this information is known for the 58 per cent of respondents who comprised the second wave; 43 per cent of these respondents were doctors and 57 per cent were nurses.

Factors restricting organ harvest

Respondents were presented with a list of nine factors and asked to say about each whether it restricted the harvesting of organs from their own unit. A choice of three replies (yes, possibly, no) was given.

No single factor was universally accepted as limiting organ harvest (*Table 3*). The factor identified with greatest frequency was dislike of adding to relatives' distress. Next in perceived importance was lack of training in how to approach relatives.

Table 4 *Differences between intensive care unit doctors and nurses in perceived restrictions on organ harvest from their own units*

		Respondents' views on whether certain factors restrict organ harvest (%)		
Factor	Group	Yes	Possibly	No
Lack of training in how to approach relatives*	Doctors	4	33	63
	Nurses	28	31	41
Adverse media publicity about brain stem death/ transplant procedures†	Doctors	13	15	72
	Nurses	19	28	53
Lack of unit policies etc. regarding brain stem death and subsequent referral‡	Doctors	1	9	90
	Nurses	10	11	79

Percentages calculated from a maximum of 213 responses $*\chi^2=21·41$, d.f.=2, $P<0·0001$, $\dagger\chi^2=8·02$, d.f.=2, $P<0·02$, $\ddagger\chi^2=7·85$, d.f.=2, $P<0·02$

Some reasons suggested by initial telephone interviews as potentially important proved not to be so. In particular, there was very little evidence that ICU staff see resentment of the time, effort and expense of organ referral as a disincentive, or that reservations about the validity of brain stem death criteria play a part in discouraging organ harvest.

Analysis of subgroups revealed certain significant differences in opinion between doctors and nurses (*Table 4*). Nurses more than doctors thought lack of training in how to approach relatives restricted organ yield. Similarly, more nurses than doctors thought lack of unit policies on brain stem death and referral limited organ procurement.

There was little suggestion of important differences in attitude between respondents from different types of hospital or unit. However, those respondents who regarded adverse experiences with members of transplant teams as a factor in organ availability were not randomly distributed according to hospital type. Fifteen per cent of respondents from teaching hospitals thought such experiences definitely restricted harvesting in their units, compared with 11 per cent of respondents from district general hospitals with regional specialties and 4 per cent of respondents from other district general hospitals ($P<0·01$).

Developments that might encourage referral of organs

Respondents clearly felt that a number of measures would or might increase referral of potential donors (*Table 5*). 'Enhanced public awareness of the need for transplantation' was the most popular of the five suggestions put to them, followed by encouraging medical and nursing staff to regard referral of organ donors as their duty.

The impact of an opt-in system (in which donor cards would be replaced by a national computer record) and an opt-out system (in which clinicians could assume patients had agreed to organ donation unless they had previously registered an objection) were thought similar in their likely effects on referral. However, the ethical problems posed by an opt-out system were reflected in the fact that 8 per cent of respondents added comments to their reply forms indicating that they would not be prepared to implement such a system.

Required request, whereby doctors are legally obliged to ask relatives of medically eligible patients for permission to use their organs, was also strongly objected to by a significant proportion of respondents. Nineteen respondents (5 per cent of the total) felt strongly enough about the issue to write in comments, eight were hostile to required request ('dangerous', 'disastrous', 'I would refuse to implement such a system', were among the remarks) Nevetheless, more than a quarter of respondents thought required request would increase organ supply, and more than half either thought that it would make no difference or that it might help There was a difference between medical and nursing staff on the issue ($P<0·001$): 36 per cent of nurses thought required request would increase organ yield, but only 17 per cent of doctors did so. Fifty per cent of doctors, compared with 27 per cent of nurses, thought required request would make no difference.

Discussion

While it must be remembered that our data were collected by anonymous questionnaire and must therefore be interpreted with caution, the general survey of medical opinion shows little doubt about the popularity of the transplant programme, although hearts and livers lag behind kidneys and corneas in support. Opinion in favour of transplantation was evenly spread across specialties; there was no evidence, for example, that surgeons were more in favour than physicians, or that hospital staff were more in favour than GPs.

Senior medical and nursing staff who have the opportunity, many would say, the responsibility, to refer brain stem dead patients for organ donation, perceive a number of obstacles to increased rates of referral. Though no single factor stands out as limiting the current harvest of organs, the three factors most frequently seen to be important (dislike of adding to relatives' distress, lack of training in how to approach relatives, and adverse media publicity) all relate to the interaction between the medical profession and the public. There is little suggestion from our data that questions of organization or administration or of medical ethics lie at the root of the organ shortage. In particular, in view of the well publicized objections of individual clinicians[7], it is important to have established that the senior medical and nursing staff who deal with potential organ donors see few problems arising from the validity of current criteria of brain stem death. In the light of authoritative reports[8,9], it appears to be widely accepted by ICU staff that brain stem death invariably heralds asystole. There also appears to be little worry on the part of senior ICU staff about the time, effort and expense of referring potential organ donors. Of course, these are the views of the senior staff involved it is possible that registrars and others who may initiate contact with the transplant team could feel differently, but we were unable, given our resources, to survey them.

Our findings are in broad agreement with those of recent surveys of neurosurgeons and ICU nurses in the USA[10]. Prottas and Batten concluded that reservations regarding the clinical aspects of organ donation are not important factors in limiting organ harvest Of far greater significance is the unwillingness to confront relatives with the diagnosis of brain stem death and the request for permission to harvest organs.

Table 5 *Developments seen by intensive care unit staff as encouraging referral of potential organ donors from their own units*

	No responding (from a maximum of 213)		
	Would help	Might help	Would make no difference
Replacing donor cards by national computer record (opt-in)	96 (26)	146 (40)	126 (34)
System of 'required request'	101 (28)	116 (33)	138 (39)
Enhancing public awareness of the need for transplantation	276 (74)	58 (16)	39 (10)
An opt-out system	102 (29)	108 (31)	140 (40)
General encouragement of medical and nursing staff to regard referring organ donors as their duty	151 (41)	102 (28)	114 (31)

Values in parentheses are the percentages of those responding to each item

In our study, nurses particularly tended to emphasize the importance of adequate training in how to approach relatives. They also emphasized the importance of establishing procedures for arranging organ donation, giving the clear impression that nursing staff in ICUs are less sanguine about the adequacy of present arrangements than are their medical colleagues. This impression also has relevance to one of Prottas' and Batten's conclusions[10]. In this study, neurosurgeons appeared substantially more reluctant than ICU nurses to approach bereaved relatives.

Of the recommendations in the Report of the Royal Colleges[1], we are able to endorse the need for education of the public (in respect of the need for organ donation, as well as about the safety of the brain stem death criteria) and of the medical profession (in communication with bereaved relatives). In relation to public education, there would appear to be a considerable opportunity for GPs to play a major part Regarding doctors, there is now overwhelming evidence that enhancing their communication skills is quite possible[12]. But we also find evidence that the referral of organ donors could be increased if it were accepted by the staff responsible that this was part of their professional duty.

Although a significant proportion of our respondents in ICUs thought that both legally required request and an opt-out system of refusing donation would increase organ harvest, the antipathy shown by others would seem to make both ideas difficult to implement in the UK. It has also been effectively argued on the basis of experience in the USA that required request is likely to make little impact on organ harvest, as ending the physician's discretion in such matters is far more difficult to achieve in practice than in theory[11].

The education of the public regarding the need for organs and the safety of the brain stem death criteria, and of the professionals in communication with bereaved relatives, ought to be relatively straightforward and uncontroversial to arrange. We conclude that this should take precedence over any more coercive measures.

Acknowledgements

The three surveys reported were made possible by financial assistance from Sandoz Pharmaceuticals: we are grateful for this support We also thank the BBC 'That's Life' team for their encouragement and help, Celia Wight (transplant co-ordinator at Cambridge) for her invaluable advice, and the transplant co-ordinators, medical and nursing staff and members of the public who generously gave of their time to be interviewed and to complete questionnaires

It has long been recognized that curative surgery as the sole treatment for rectal cancer yields disappointing results. There is now a growing body of evidence from prospective randomized clinical trials to support the role of adjuvant therapy for patients whose primary tumour has spread through the rectal wall or has associated lymph node involvement. Carefully planned radiation therapy with adequate doses and fields can reduce the risk of locoregional failure. Chemotherapeutic agents delivered either systemically or regionally may also contribute to better disease control and survival. A number of diagnostic and therapeutic issues still need to be addressed in order to use the available adjuvant treatment methods most appropriately. Efforts to refine patient selection, to enhance therapeutic effect and to minimize toxicity are likely to improve the outlook for patients with resectable rectal cancer.

Keywords: Rectal cancer, adjuvant therapy, review, randomized prospective clinical trials

Data from a growing number of clinical trials indicate that adjuvant therapy plays an important part in the overall management of patients with resectable rectal cancer Local control and overall survival appear to be enhanced if definitive surgery is combined with irradiation and chemotherapy.

The purpose of this review is to emphasize the limitations of surgery alone in certain subsets of patients with rectal cancer and to examine critically the advantages and disadvantages of adjuvant treatment methods. We also describe the major current trials and suggest areas of future study necessary to address some of the unanswered questions regarding multimodality therapy

Results with surgery alone

Overall survival

The majority of patients (71–93 per cent) with node-negative rectal cancer are cured by radical surgical resection[1–3]. In contrast, only a minority of patients (29–41 per cent) whose rectal cancers have spread to regional lymph nodes are cured by surgery[1–3]

Locoregional failure

Achieving locoregional disease control at the time of primary treatment is of paramount importance Not only can pelvic recurrence lead to disabling symptoms, but treatment of symptomatic recurrence is usually unsatisfactory. It is likely that most cases of pelvic recurrence after radical surgery are related to direct microscopic radial spread[4] and/or intralymphatic tumour cells[5]. The recurrence of pelvic tumour is directly related to the extent of transmural tumour penetration and to the presence of lymph node metastases[6–12]. This is shown in relation to pathological stage in *Figure 1*. Although local recurrence may occur in 22–67 per cent of node-positive patients treated only with surgery, it is frequently accompanied by evidence of distant metastases (10–61 per cent)[6,10–12].

Failure patterns determined at autopsy provide insight into the relative risks of local and distant recurrence. In the series from the Massachusetts General Hospital[6], isolated pelvic recurrences were documented in 25 per cent of patients, but a total of 75 per cent of cancer-related deaths were associated with tumour in the pelvis. These data would suggest that improved local control of the primary cancer and regional nodes may not only reduce cancer-related morbidity but may also improve survival

Distant metastases

The relatively disappointing long-term cancer-specific survival rate after curative surgery has been largely explained by the occurrence of occult metastatic disease In 1941 Goligher studied 790 consecutive rectal cancer patients who were considered to have no metastatic liver disease at the time of laparotomy[13]. Thirty patients died in the immediate postoperative period and at autopsy, five (17 per cent) of these patients had histological evidence of liver metastases. In a more recent study, a group of colorectal cancer patients treated for cure were followed prospectively with frequent liver imaging[14] Within 2 years 29 per cent had developed liver metastases, suggesting that these had been present but undetectable at the time of primary treatment.

Radical surgery and adjuvant irradiation

There is a considerable body of data from non-randomized studies which suggests that adjuvant radiation therapy can reduce the pelvic recurrence rate. While these data cannot be used to provide scientific validation of the usefulness of this

adjuvant treatment, they can provide valuable background information regarding radiation dose, sequencing and field size Our end-results discussion will be restricted to the relatively few studies in which the patients were randomized.

Radiation dose considerations

There appears to be a trend indicating improved local control as the preoperative dose of radiation therapy is increased[15]. One recent preoperative radiotherapy study[16] examined local control rates with varying doses of radiation. The local control rate at 4000 cGy was 67 per cent, increasing to 91 per cent at 5000 cGy. Another study demonstrated a local control rate of 67 per cent with doses between 5000 and 5499 cGy, increasing to 89 per cent with doses greater than 6000 cGy[17]. It seems apparent that doses of at least 5000 cGy are needed to control microscopic disease if the fraction size is 180–200 cGy per day. Data from randomized trials that have used doses less than 3500 cGy have shown benefit only if the fraction size is 230–500 cGy per day[18].

Sequencing considerations

The integration of radiation therapy and surgery can involve preoperative or postoperative irradiation, or a combination of the two. Preoperative radiation therapy minimizes the risks of tumour cell implantation during surgery and may be most effective against the well-oxygenated cancer cells at the periphery of the tumour mass. These benefits are balanced by the problems in case selection (under- or over-treatment) and by the potentially increased surgical complication rates. Postoperative radiation therapy allows careful case selection based on operative findings and pathological staging. However, residual cancer cells may be hypoxic and less radiosensitive, and the risk of small bowel damage is greater.

The so-called 'sandwich' radiotherapy technique involves preoperative radiation therapy, usually with relatively small doses (500–2000 cGy), followed by postoperative radiation to a higher total dose for high-risk cases. Enthusiasts for this method believe that the advantages of both preoperative and postoperative radiotherapy are combined.

Field size

With the radiation doses that must be used to control microscopic disease the major organ at risk for injury is the small bowel If a large portion of the small bowel receives more than 5000 cGy, there is an increased risk of complications such as obstruction, perforation or fistula formation. The volume of the treatment field is an important determinant of the risk of small bowel damage. Preoperative field sizes can be smaller than those considered adequate in the postoperative setting. The short-term effects are related to the volume of small bowel treated while the long-term effects are related to the volume of small bowel receiving a dose greater than 4500 cGy and a history of prior pelvic surgery[19].

Techniques to minimize small bowel toxicity

In addition to the field volume, small bowel complications also relate to the radiation energy, fraction size, total dose, technique and overall treatment duration. The risk of complications may be influenced by other patient-related factors such as age, body habitus, sex, atherosclerosis, hypertension or diabetes. Many techniques[20–30] have been developed to minimize toxicity. These include excluding the small bowel from the pelvis by peritoneal repair, retroversion of the uterus, omental flaps[21] and insertion of absorbable mesh[22] or porcine dermis[23]. As in surgery, radiation technique influences complications. Considerations include using small bowel contrast during treatment planning, multiple fields, prone treatment, bladder distension and abdominal compression. Recent approaches have studied diet regulation[26–28] and the use of radioprotective agents[29,30].

Results in randomized trials with adjuvant radiation therapy

Preoperative radiation therapy

A summary of the major randomized preoperative studies[18,31–37] is shown in *Table 1*. Relatively low doses varying from 500 to 3450 cGy were used with various fraction sizes and treatment durations. Low dose levels with small fraction size

Table 2 *Randomized postoperative radiation therapy studies*

RT, postoperative radiation therapy; DFS, disease-free survival

appear ineffective. 'Suboptimal' dose levels with a large fraction size appear to reduce local failure[18].

The most impressive results are those reported by the European Organisation for Research on Treatment of Cancer (EORTC)[36]. In this study 341 patients were randomized to preoperative radiation therapy using 15 fractions of 230 cGy per day over a 19-day span *versus* surgery alone. At 5 years, the actuarial local disease-free survival rate was 85 per cent for the preoperative radiotherapy group compared with 70 per cent for the surgery alone group. The Stockholm Rectal Cancer Study Group analysed 545 patients who had potentially curative surgery Half had received 2500 cGy over 5–7 days preoperatively. The pelvic recurrence rate was halved by irradiation ($P<0.01$).

In the studies with doses below 3000 cGy, there has been no reported improvement in overall survival An exception is the Veterans Administration Surgical Oncology Group (VASOG) I study[32] in which patients who had preoperative irradiation (2500 cGy) and abdominoperineal resection had a 41 per cent 5-year survival rate compared with 28 per cent for those having surgery only. Of the studies using doses higher than 3000 cGy, the EORTC[36] reported a difference in disease-free survival between the two groups. With a median follow-up of more than 4 years, the overall actuarial 5-year survival rate in the radiated patients was 10 per cent greater than the surgery alone group, but this reaches only the $P=0.08$ level of significance.

Two studies from the USSR[38,39] have shown statistically significant increases in survival, but it is not clear whether they were properly randomized.

In terms of complications with low-dose radiotherapy, the most complete observations were made in the UK Medical Research Council study[35]. In this study, the complications were essentially identical between the two radiotherapy groups and the surgery alone group with the exception that there was a significant decrease in anastomotic leak rate in the radiotherapy groups compared with the surgery alone group. No increase was observed in the risk of long-term complications. In the VASOG II[37] and the EORTC[36] studies most complications were similar in treated and control groups except for an increase in perineal wound infections in the radiotherapy groups

Postoperative radiation therapy

There have been three major randomized studies that include a 'surgery only' arm compared with postoperative radiation therapy. These reports, summarized in *Table 2*, were from the Gastrointestinal Tumor Study Group (GITSG)[40,41], the National Surgical Adjuvant Breast and Bowel Project (NSABP)[42] and a consortium of institutions in Denmark[43]. Statistically significant improvements in local control have not been shown. However, in the two studies that have been fully reported[40,42] protocol violations were frequent. In the largest trial (NSABP), the local recurrence rate was reduced from 25 to 16 per cent with radiation therapy ($P=0.06$).

No survival difference has been seen at 5 years in any of these studies, although the study from Denmark is not yet mature. In the GITSG trial there was a trend towards an increased survival rate in the radiation therapy group (52 per cent) *versus* the surgery only group (45 per cent). It is of interest that only after 5 years is there a significant survival difference in the combined chemotherapy–radiation arm in this trial This suggests that in any of these studies a decrease in local recurrence rate may not translate into a survival advantage for many years

Adjuvant systemic single agent chemotherapy

Multiple randomized trials of adjuvant 5-fluorouracil (5-FU) in colorectal cancer patients have not demonstrated any consistent benefit However, three groups[44–46] reported rectal patients separately, with an improvement in survival in two studies. The negative trial[44] used an unsatisfactory regimen of oral 5-FU administration and randomized 156 patients, 55 of whom had rectal cancer. All patients received intraluminal 5-FU. The treated group subsequently received two doses of intravenous 5-FU (10 mg/kg), then five 18-day cycles of oral 5-FU The results of this trial were negative, but the number of rectal cancer patients analysed was too small to detect a modest improvement in survival.

Higgins and colleagues in the Veterans Administration Surgical Adjuvant Group entered colorectal cancer patients in several adjuvant chemotherapy studies including an assessment of prolonged intermittent treatment with 5-FU[45] Two hundred and fifty-seven patients with either T2,N1–2, T3–4,N0–2 rectal cancer or any local stage with evidence of vascular invasion were randomized to surgery alone or to surgery and adjuvant 5-FU. The 5-FU was given on five successive days as an intravenous bolus (12 mg/kg), repeated every 6–8 weeks for 18 months. There was a small survival advantage for the treated patients, which in those requiring an abdominoperineal resection reached an almost 10 per cent survival rate advantage at 5 years (43·3 per cent for treated patients *versus* 33·7 per cent for controls)

Grage and members of the Central Oncology Group entered 394 colorectal cancer patients in a study of intensive adjuvant 5-FU[46] The treatment programme involved intensive intravenous 5-FU pushed to toxicity for 12 days, followed by weekly 5-FU (12 mg/kg) for 1 year. Of the fully evaluable patients who had a potentially curative resection, 64 rectal cancer patients were analysed separately The overall incremental survival rate in the 5-FU group was 20 per cent after a follow-up of 29 months ($P=0.005$).

Table 3. *Recently completed rectal cancer postoperative adjuvant trials*

Study	Protocol	Dukes' classification	Patient accrual	Treatment	No of evaluable patients
Gastrointestinal Tumor Study Group[40,41]	7175	B_2, C	227	Control	58
				MF	48

				Pelvic RT	177
				MOF	178

All patients underwent a complete surgical resection M, methyl CCNU; O, vincristine, F, 5-fluorouracil; RT, radiation therapy

Adjuvant combination chemotherapy and combined chemotherapy: radiation therapy

In order to minimize local and distant disease recurrence after primary resection, various combinations of surgery, pelvic radiation therapy and systemic chemotherapy have been evaluated[47]. Three recently completed randomized studies[40–42,48] are of particular relevance. As summarized in *Table 3*, these studies evaluated postoperative pelvic radiotherapy and combination chemotherapy together. Two had surgery only control groups[40–42] and two had combined radiation and chemotherapy groups[40,48].

The GITSG trial[40,41] was initiated in 1975 and allocated completely resected Dukes' B_2 and C patients to one of four groups: surgery alone; methyl CCNU (130 mg/m^2 on day 1) and 5-FU (325 mg/m^2 on days 1–5, then 375 mg/m^2 on days 36–40), the cycle being repeated every 10 weeks for 18 months; 4400–4800 cGy to the pelvis; 4000–4400 cGy plus 5-FU/methyl CCNU as above. At a median follow-up time of 80 months the control population had a 55 per cent recurrence rate compared with a 33 per cent rate for the combination radiotherapy–chemotherapy group ($P<0.009$). In the control group 14 of 32 patients had a local recurrence compared with five of 46 patients in the combination therapy group. A subsequent analysis at 94 months' median follow-up demonstrated an even larger margin of benefit for the combination therapy group[41]. In addition to a disease-free survival advantage, the combination radiation–chemotherapy group demonstrated a statistically significant overall survival benefit ($P=0.005$). There was an approximately 20 per cent increase in survival rate at 6 years for the 96 patients at risk.

The second major rectal cancer adjuvant trial was initiated by the North Central Cancer Treatment Group (NCCTG) in 1979[48]. A total of 200 Dukes' B_2 and C rectal cancer patients were randomly assigned to either postoperative radiotherapy alone (4500 cGy with a 500-cGy boost) or to an integrated programme of methyl CCNU (130 mg/m^2 on day 1) plus 5-FU (350 mg/m^2 on days 1–5 and 400 mg/m^2 on days 36–40), radiation beginning on day 64, followed by one additional cycle of methyl CCNU plus 5-FU. The radiation dose was 4500–5000 cGy. At a median follow-up time of 29 months, there were 38 recurrences in the radiotherapy group compared with only 23 in those receiving the combination. There was a doubling of the disease-free survival rate in patients undergoing sphincter-saving surgery followed by the combination treatment compared with postoperative radiotherapy alone. The local failure rate in the combination treatment group was 11 per cent *versus* 20 per cent with irradiation only. The overall disease-free survival rate was superior with combined treatment ($P=0.001$) The time interval to tumour recurrence was statistically superior for the combination therapy group ($P=0.025$). Overall survival differences could not be reported since the data were not sufficiently mature.

The largest study was performed by the NSABP[42]. A total of 528 Dukes' B_2 and C patients were randomized to receive: postoperative observation; postoperative pelvic radiotherapy, 4700 cGy with a boost to a maximum of 5300 cGy; or 18 months of chemotherapy with methyl CCNU, vincristine and fluorouracil (MOF). A combination chemotherapy–radiation arm was not included in the study design. With a 54-month mean follow-up time, there was a statistically significant disease-free survival advantage for MOF chemotherapy ($P=0.05$) and an overall survival improvement only for selected MOF-patient subsets, particularly men ($P<0.02$) and most notably men aged less than 65 years ($P<0.001$) Patients receiving only radiotherapy had no statistically demonstrable improvement in overall or relapse-free survival. In this group, however, there was a reduction in locoregional recurrence rate attributable to radiotherapy from 25 to 16 per cent, although this was not found to be statistically significant ($P=0.06$). Despite the 80 weeks of MOF chemotherapy, leukaemia has not yet been observed[49].

In contrast to the above studies[40,44,48], the EORTC study was unable to show a benefit with combined treatment[50]. This study of preoperative adjuvant therapies compared irradiation with 3400 cGy in 230-cGy fractions to the same radiation dose combined with only 4 days of intravenous bolus 5-FU (375 mg/m^2) during the first 4 days of radiotherapy. In the 247 patients followed, overall survival was better with radiotherapy alone. Although the incidence of liver metastases was reduced in the combined radiation–chemotherapy group, this was not statistically significant ($P=0.07$).

While adjuvant combined modality therapy may yield improved survival, there is the potential for considerable treatment-related morbidity. In the initial GITSG report[40] the acute toxicities encountered were considered generally acceptable, with 25 per cent of those receiving both radiotherapy and chemotherapy having a white cell count lower than 2000/mm^3. However, the morbidity related to treatment in the GITSG trial[41] was in fact quite extensive and was the subject of a separate report[51]. Severe or life-threatening acute toxicities occurred in 18 per cent of patients in the radiotherapy arm and in 61 per cent of those in the combined radiotherapy–chemotherapy arm. Three late deaths occurred. two from radiation enteritis in the combined treatment group and one from non-lymphocytic leukaemia in a patient receiving chemotherapy alone. There is good evidence to show that radiation-induced morbidity can be minimized by using some of the techniques previously mentioned Many of these precautions were not observed in this trial.

Specific unresolved issues and current studies

Radiation therapy and/or surgery sequencing issues

In relation to radiation therapy sequencing techniques, two major studies are currently active. In Sweden a multicentre trial was launched in late 1980 to compare randomly pre-operative and postoperative radiotherapy for resectable rectal cancer. The preoperative treatment consists of five fractions of 510 cGy to a total tumour dose of 2550 cGy delivered in 5–7 days. In the postoperative treatment group, only patients with Astler–Coller stages B2, C1 and C2 are irradiated. After the first 4 years of the trial, when 360 patients had been randomized, an interim report was prepared[52]. It is of note that in the preoperative treatment group the radiation was well tolerated, the only significant problems encountered being an increase in perineal wound sepsis and an increase in the mean duration of hospital stay. For the postoperative group considerable difficulties were encountered in completing the programme of irradiation. A total of 8 per cent of the preoperatively treated group had disease limited to the mucosa and submucosa compared with 6 per cent of the remainder Using life table analysis local recurrence rates were 10 and 12 per cent respectively for the preoperative and postoperative treatment groups

The Radiation Therapy Oncology Group (RTOG) together with the Eastern Co-operative Oncology Group (ECOG) are conducting a phase III randomized trial of 'sandwich' radiotherapy *versus* postoperative radiotherapy alone for Dukes' A, B and C rectal cancer. Patients are randomly allocated to receive preoperative radiation (500 cGy) or not. After surgery all patients with Dukes' B_2 or C disease receive 4500 cGy to the pelvis.

Prognostic issues

Selection of patients for preoperative irradiation remains uncertain. Clinical, radiological and biological studies may be able to define the high-risk group most likely to benefit from preoperative irradiation Intraluminal rectal ultrasonography has proved to be an accurate means of defining the extent of transmural invasion. It is somewhat less reliable in the accurate diagnosis of perirectal nodal metastases[53]. Combined with clinical staging[54], it may allow definition of those patients most suitable for preoperative radiation therapy.

DNA distribution was first recognized as a possible prognostic factor for rectal cancer in 1982[55]. Indeed, striking differences were noted in outcome when patients with predominantly diploid tumours were compared with those with the more aggressive non-diploid lesions. DNA ploidy has not been universally found to be an independent prognostic indicator, especially when examined in a multivariate fashion It has however been shown to be a prognostic discriminant in univariate analysis, and as it can be assessed on preoperative biopsy material it may yet prove to be worthy of consideration[56,57].

The extent to which transforming cellular oncogene expression is related to the clinical behaviour of tumours continues to be of great interest[58] It has been suggested that the expression of *ras* family oncogenes may be related to disease progression; for example, *c-myc* over-expression was associated with a much greater chance of early recurrence of cervical cancer[59]. In a small group of patients *ras* gene activation has been associated with the depth of invasion of colorectal cancer[60] while others have failed to demonstrate any relationship with clinical outcome[61].

Laparoscopy is a convenient technique to detect both macroscopic peritoneal metastases and deposits visible on the surface of the liver. For gastric cancer it has been shown to be an accurate method of detecting previously undetected liver metastases[62,63] although neither of the studies reporting its value made use of preoperative computed tomographic scanning. The extent to which laparoscopy can add to the available methods for detecting previously occult metastases in rectal cancer remains unexplored

The use of monoclonal antibodies in radioimmunodetection of regional nodal metastases and distant disease remains at an early investigational stage[64].

Radiation treatment issues

Crucial to the efficacy and toxicity of radiation therapy is both fraction and treatment portal size. Preoperative irradiation to 5040 cGy in fractions of 180 cGy per day needs to be compared with doses of 2500–3500 cGy in fraction sizes as great as 550 cGy. In such a study, local control and both early and late complication rates must be compared Advances in computerized three-dimensional treatment planning may dramatically reduce radiation-induced toxicity.

Chemotherapy issues

Issues relating to systemic chemotherapy agents are being investigated in two ongoing large co-operative randomized trials in the USA (*Table 4*). The NCCTG study 86-4751 utilizes a 2 × 2 factorial statistical design and attempts to quantify the relative benfits of continuous infusion *versus* bolus 5-FU as well as the necessity of including methyl CCNU in the chemotherapy regimen All patients receive pelvic radiotherapy and concomitant 5-FU in the sequence chemotherapy–radiation–chemotherapy. Half the patients receive methyl CCNU plus 5-FU chemotherapy as in the previous NCCTG trial; the other half receive 5-FU, 500 mg/m^2 on days 1–5 and on days 36–40 before radiation, and 450 mg/m^2 on days 1–5 and on days 36–40 1 month after radiation. During radiotherapy, patients receive either standard 5-FU, 500 mg/m^2 on days 1–3 and on days 36–39 as an intravenous bolus, or a continuous intravenous infusion at 225 mg/m^2 daily for 5 weeks The planned pelvic radiotherapy dose consists of 4500 cGy with a boost to a total of 5400–5900 cGy.

In male patients, the recently activated NSABP R-02 study compares their standard MOF chemotherapy with a 5-FU/leucovorin programme and is complementary to their C-03 study for colon cancer patients.

The integration of portal and systemic venous chemotherapy must be considered if benefit is confirmed in colon cancer. The rationale for adjuvant perioperative intraportal chemotherapy is based on the observation that, at the time of surgery, tumour cells embolize into the portal venous system and reach the liver[65,66]. Fisher and Turnbull[67] demonstrated tumour cells in the portal circulation in 32 per cent of patients at the time of colonic carcinoma resection. Moreover, there is considerable clinical and autopsy evidence that the liver may be the most frequent, and sometimes the only, site of metastasis[65,66]. Although established metastases are supplied primarily by the hepatic artery, micrometastases are likely to be dependent on the portal venous blood supply[68]

In 1975 Taylor *et al.*[69] began a randomized study comparing intraportal 5-FU (700 mg/m^2 per day) with heparin for patients with Dukes' A, B and C colorectal cancer. A continuous 7-day infusion was started in the immediate postoperative period.

Table 4 *Currently active North American co-operative group rectal cancer postoperative adjuvant trials*

Study	Projected accrual	Treatment
North Central Cancer Treatment Group (86-4751)	450	MF, RT + F infusion, MF MF, RT + F bolus, MF F, RT + F infusion, F F, RT + F bolus, F
National Surgical Adjuvant Breast and Bowel Project (R-02)	800	Men MOF MOF + RT F + leucovorin F + leucovorin + RT Women F + leucovorin F + leucovorin + RT
National Cancer Institute, Canada (CO-4)	425	RT F + leucovorin, RT, F + leucovorin

All patients undergo complete surgical resection; pathological stage T3N0M0 or TXN1-2M0 (modified Astler–Coller B_2/C). M, methyl CCNU; F, 5-fluorouracil, O, vincristine, RT, radiation therapy

Two hundred and twelve patients were studied and, by 1985, 80 deaths had occurred. The median follow-up was greater than 50 months. The Dukes' B colon cancer group appeared to have a substantial survival benefit ($P = 0.002$) with intraportal venous 5-FU. This preliminary study stimulated several randomized trials of generally similar design. In Australia and New Zealand a trial evaluated 372 colon cancer patients randomly allocated to observation alone or to immediate postoperative chemotherapy, 5-FU 600 mg/m^2 daily for 7 days given either intravenously or intraportally. Compared with both of the other groups, portal vein 5-FU resulted in highly significantly superior disease-free and overall survival rates[70]. These data are not fully mature and require further follow-up in order to determine the magnitude of the survival benefit. A second study of similar design was conducted by the Swiss Group for Clinical Cancer Research (SAKK)[71]. From 1981 to 1986, 378 evaluable Dukes' A, B or C patients who had complete resection of colorectal cancer were allocated either to a control group or to a chemotherapy group receiving immediate postoperative intraportal 5-FU (500 mg/m^2 daily) with 5000 units heparin given by continuous infusion for 7 days. On the first day of therapy, a 10 mg/m^2 bolus of mitomycin C was also administered. After a median follow-up of 24 months, recurrences were detected in 43 of 187 (23 per cent) control patients compared with 34 of 191 (18 per cent) infused patients ($P < 0.05$). Too few deaths have occurred to permit a significant difference in survival to be detectable, and a longer follow-up period is required before conclusions can be definitely drawn.

There are two active phase III trials evaluating colon cancer patients in the USA. Of special importance is the NSABP C-02 study as, with 1334 patients, it will be the largest single portal vein trial. It is anticipated that both studies will complete accrual in 1988 and that preliminary survival data will be available 1–3 years thereafter

Systemic chemotherapy–radiation therapy interaction

The recently activated NSABP R-02 study will attempt to confirm the GITSG and NCCTG results which indicated that both local control and overall disease-free survival were maximized by combining chemotherapy with pelvic irradiation. Male patients will be randomized to methyl CCNU/vincristine/5-FU (MOF) *versus* 5-FU/leucovorin. Half of the patients will receive radiotherapy in conjunction with chemotherapy. Because of the suggestion that the benefits of MOF were limited to men[42], women will receive 5-FU/leucovorin with or without radiation while men will be randomized amongst the four therapy options. The National Cancer Institute, Canada, NCIC CO-4, protocol will evaluate an integrated programme of 5-FU/leucovorin chemotherapy and X-ray therapy in comparison to postoperative pelvic radiotherapy alone.

The integration of postoperative chemotherapy and irradiation may lead to improved survival, but with excessive toxicity[40]. Comparisons of the therapeutic ratio obtainable with surgery–X-ray therapy–chemotherapy sequencing (NSABP) must be compared with the surgery–chemotherapy–X-ray therapy–chemotherapy (NCCTG) approach. The integration of chemotherapy into the preoperative irradiation approaches has yet to be explored Sequential *versus* simultaneous chemotherapy/X-ray therapy approaches must be compared.

Biological response modifiers

An immunotherapy regimen, either alone or in combination with chemotherapy, was used in the adjuvant treatment of colon cancer, with mixed results[72] Adjuvant immunotherapy has not been definitively tested in rectal cancer patients. In a study from Leicester[73], 141 colorectal cancer patients were randomized to receive either surgery alone, surgery plus 5-FU (1·0 g intravenously after operation and repeated on the first two postoperative days then 1·0 g orally every week for the next 6 months), or surgery plus 5-FU with the addition of the non-specific immunostimulant levamisole (150 mg orally on each of the first three postoperative days). With a minimum follow-up of 5 years, the cancer-specific survival rate was 48 per cent for the controls, 56 per cent for the chemotherapy group and 68 per cent for the combination therapy group. A strongly positive trial of adjuvant 5-FU and levamisole has also been reported by the NCCTG[74]. The current Intergroup 0035 study is attempting to confirm these data

Other approaches undergoing trial in colon cancer patients include the use of BCG and autologous tumour cell vaccine (ECOG, EST-5283) and recombinant interleukin 2 (Illinois Cancer Council, ICC-8614).

If the efficacy of any of these approaches in colon cancer is demonstrated, biological response modifiers will have to be integrated into the already complex multimodality rectal cancer regimens.

Current recommendations based on the above data

The randomized studies described indicate that meaningful survival benefits can be achieved with programmes of postoperative adjuvant chemotherapy. Preoperative or postoperative radiation therapy can reduce the risk of developing potentially catastrophic local recurrence. The combination of radiation and chemotherapy may offer the greatest survival advantage[47]. What remains unclear is: the exact choice of chemotherapeutic agents to maximize overall survival and to minimize toxicity; the route of administration and duration of these drugs; the scheduling and dosage of radiation; and the logistics of integration of all three methods of treatment (surgery, radiation therapy and chemotherapy).

While awaiting the complete analysis of the ongoing studies, some form of adjuvant therapy is recommended for most patients with extraperitoneal rectal cancer with transmural penetration and/or positive lymph nodes. The case seems most convincing for patients whose primary tumours invade locally into adjacent structures or where there is gross transmural extension with involved lymph nodes. Whenever possible, participation in a formal clinical trial is to be encouraged However, for those not entering a clinical study, the choice of adjuvant therapy is contingent on many medical, psychological and social factors which must be considered by the patient and physician. For many patients the use of preoperative or postoperative radiation therapy with postoperative 5-FU chemotherapy is a reasonable programme at present.

Gallbladder carcinoma continues to be a discouraging disease. Prognosis after resection still remains poor. Radiation therapy has been used in an attempt to improve the prognosis but only a few series of less than ten cases have been reported. Since 1977 we have treated 20 patients with gallbladder carcinoma with postoperative radiotherapy (mean total dose 4200 radiation absorbed dose). In four patients all the tumour was resected with the intent of cure. In 12 patients, the lesion was partially resected and in four patients no resection was performed. Seven patients in whom the tumour was partially resected or not resected also had chemotherapy. Our evaluation was retrospective and we compared our results with historical control groups comparable with respect to surgical procedures and pathological staging. In patients operated on for cure, one patient is alive at 84 months, the others died at 7, 8 and 33 months. In patients in whom the tumour was partially resected the mean survival time was 8·1 months and two patients are still alive 7·0 months after treatment. According to the Nevin classification the mean survival time in stage IV and V patients was respectively 9·2 and 7·2 months. There was no difference in survival between patients treated or not treated with chemotherapy. This experience is the largest published and suggests that radiotherapy may increase survival after no resection or palliative resection of gallbladder carcinoma.

Keywords: Gallbladder carcinoma, radiotherapy

Gallbladder carcinoma is found in 1–2 per cent of patients who undergo surgery on the biliary tract[1]. It is characterized in most clinical reports by late diagnosis, ineffective treatment and poor prognosis. Actual procedures performed on 3000 patients drawn from 87 series included biopsy alone in 34·4 per cent, palliative procedures in 23 per cent, cholecystectomy with or without hepatic resection and/or lymph node dissection in 38·8 per cent, and other procedures in 3·8 per cent of the cases[1]. Two-thirds of cholecystectomies are palliative, and one-third potentially curative[2]. The overall 1-year and 5-year survival rates in 5836 collected cases were 11·8, and 4·1 per cent respectively[1]. In patients who underwent palliative procedures, 5-year survival was achieved in 0·4 per cent[1].

Adjuvant radiotherapy has not been adequately evaluated in these patients, and therefore its value after surgery is unknown. Only a few sporadic, almost anecdotal, reports concerning the use of adjuvant radiotherapy have been reported[2–4]. No specific series presents more than ten cases, and most include carcinoma of the biliary tract with carcinoma of the gallbladder[5,6]. The aim of this report is to assess the role of postoperative radiotherapy in 20 patients operated on for carcinoma of the gallbladder.

Patients and methods

A review of the cases registry at our Division of Radiotherapy revealed 20 patients with gallbladder carcinoma who were treated postoperatively with a complete course of radiotherapy between May 1977 and November 1987. One other patient was excluded from the study because of failure to complete the planned course of radiotherapy. He refused further therapy after receiving only 1400 radiation absorbed dose (rad) of a planned 4500 rad. The remaining 20 patients constitute this series. Seven patients were men and 13 women. They ranged in age from 50 to 74 years (mean age 63·5 years). The presenting symptoms were those of biliary pain or cholecystitis (ten patients), jaundice (nine patients), and an abdominal mass (three patients). Weight loss was noted in four patients and not mentioned in the case histories of the others. Primary gallbladder carcinoma was diagnosed preoperatively in three patients. All 20 patients were operated on and were found to have single or multiple gallstones associated with the carcinoma. Three patients operated on for cholecystitis were found to have carcinoma of the gallbladder only at pathological examination.

The operative procedure was exploratory laparotomy with biopsy alone in two patients, and with palliative biliary diversion in two other patients (Roux-en-Y hepaticojejunostomy). Cholecystectomy was performed in 16 patients (partially in three of them). Additional lymph node dissection was performed in two cases, liver resection of the gallbladder wedge in two cases, and partial liver resection in two cases (one metastasectomy, and one bisegmentectomy for direct liver involvement). Other operative procedures after partial or total resection of the tumour consisted of colectomy (one case) and biliary drainage (three Roux-en-Y hepaticojejunostomy and one placement of a drainage tube into the common bile duct).

On histopathological examination all tumours were adenocarcinomas, well differentiated in 16 cases and poorly differentiated or undifferentiated in four cases. According to the pathological staging system reported by Nevin *et al.*[7], no patient was in stage I (intramucosal) or II (invasion of muscularis mucosa), two patients were in stage III (invasion of all layers of gallbladder wall), four in stage IV (cystic node involvement) and 14 in stage V (distant spread: liver or adjacent organs).

The time between initial surgery and radiotherapy was usually 3·5 weeks. Total doses given ranged from 3200 to 5500 rad (mean 4200 rad). The usual weekly dose was 1000 rad in four sessions. Patients were treated with 18×10^6 eV X-rays from a 20×10^6 eV linear accelerator (Saturne 20 CGR MeV, Buc, France). Parallel opposed anterior and posterior fields to the right upper quadrant were used. Clips placed at surgery were often used to determine the treatment fields. *Table 1* lists pertinent data on the 20 patients.

Seven patients were also given chemotherapy, the agents used and the number of sessions are listed in *Table 2*.

Results

No adverse effect or complication was noted after radiotherapy. In all jaundiced patients who had palliative biliary drainage, jaundice and pruritus disappeared after surgery and before radiotherapy. The jaundiced patients who had laparotomy and biopsy without a drainage procedure remained jaundiced after radiotherapy.

17	Bleomycin	1	6·5
18	5-Fluorouracil	2	6

* Patient still alive

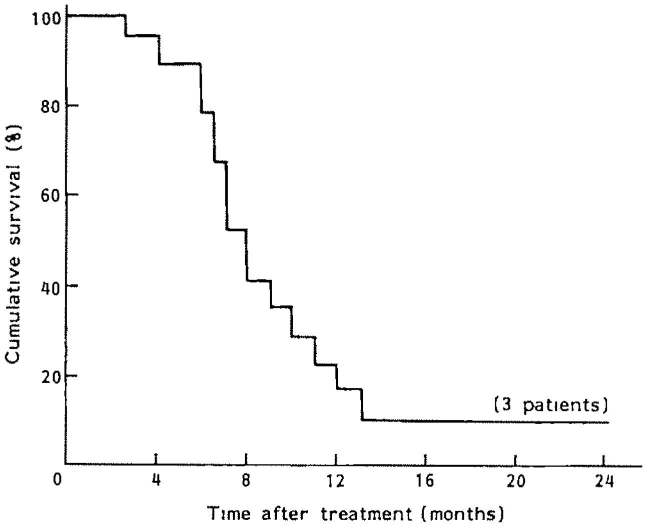

Figure 1 *Survival curve for 20 carcinomas of the gallbladder treated with postoperative radiotherapy*

The cumulative survival curve (Kaplan–Meier) for all patients is shown in *Figure 1* The median survival of the entire group was 8 months Three patients are alive, two at 7 months after partial cholecystectomy, and one at 84 months after cholecystectomy The mean survival time for the other patients was 9 months. According to Nevin's staging, the patient alive at 84 months was Nevin III, and the two patients alive at 7 months were staged Nevin IV and Nevin V respectively. The mean survival time was 9·2 months for patients staged Nevin IV, and 7·2 months for patients staged Nevin V

According to the operative procedures, two groups of patients were collected. A group of four patients in whom all of the tumour was apparently resected constituted the group operated on with intent of cure. Two tumours were staged Nevin III, one Nevin IV, and one Nevin V None of those patients received chemotherapy but all received 4500–5500 rad postoperatively (*Table 1*). In this group, one patient (Nevin III) is alive with no sign of recurrent disease at 84 months after cholecystectomy. The three others died, one 7 months after a reoperation for wedge liver and biliary tract resection (he had undergone prior cholecystectomy), while two died 8 and 33 months after cholecystectomy.

A group of 16 patients in whom the tumour was not resected or partially resected constituted the group having palliative surgery; the median survival time was 7 months but two patients were still alive at 7 months. These two patients had partial cholecystectomy, and received 3200 rad postoperatively, one of them underwent four sessions of chemotherapy. The mean survival time for the remaining patients was 7·6 months. In 12 patients from the group in which the lesions were partially resected, mean survival time was 8 1 months and median survival time was 7·5 months In four patients from the group in which laparotomy with no resection of the tumour was performed (two having palliative biliary drainage), mean and median survival times were both 6·2 months.

After palliative surgery, one patient treated with chemotherapy and one without chemotherapy are still alive. Mean survival of the remaining patients irradiated and treated with chemotherapy was 8 months, and in those irradiated without chemotherapy it was 7·2 months. The difference is not statistically significant. Survival of all patients according to pathological staging, surgical procedure and adjuvant therapy is listed in *Table 1*.

Discussion

Published reports concerning the role of radiotherapy in gallbladder carcinoma are disappointing for many reasons: (1) results are conflicting[2,5,6]; (2) whatever the results obtained, no series has exceeded ten cases and all include heterogeneous lesions[5,6,8]; (3) in almost all series the radiation dose is not specified[2,3]; (4) all specific reports of radiotherapy have included carcinoma of the biliary tract with gallbladder carcinoma[5,6,8]; and (5) the results have not been related clearly to consistent staging of the disease. This lack of evaluable data has led us to report our experience Even in large institutions there are only a few suitable cases per year and a randomized clinical trial cannot be carried out without multicentre collaboration. Thus, our investigation was retrospective and we have made comparisons with results obtained by others We have tried to evaluate the role of adjuvant radiotherapy in homogeneous groups according to pathological extension and operative procedures. Thus, we separated two groups in which the prognosis is quite different, a group operated on 'for cure' with complete resection of the tumour and its extension, and a palliative surgery group with no resection or partial resection of the tumour. If the tumour is believed to be completely resected, in spite of a poor overall 5-year survival of approximately 3 per cent[1], some authors have reported cases of prolonged survival after surgery alone[9]. This possibility and the dearth of published cases where postoperative radiotherapy has been used in these patients prompted us to try to assess the benefit of such adjuvant therapy. In our series only four patients were operated on for cure and irradiated. One is still alive, the three others died. After palliative surgery without radiotherapy, the prognosis seems well established in published series and a comparison could be performed with our own results The mean survival time of patients operated on with any tumour resection is reported to vary between 1·5 and 2 months[1,10]. In our patients irradiated after laparotomy with biopsy alone, the mean survival time was 6·2 months. In the same way, patients in whom the tumour has not been totally resected usually have a survival time of less than 6 months[1,11]. In our series the survival time for these patients seems to be improved by postoperative irradiation. Two patients were still alive 7 months after treatment, and the mean survival time for the remainder was 8 1 months. Nevin *et al* [7] have correlated depth of invasion and histological grade of tumour with survival and the mean survival time was less than 6 months for stage IV and V cases Morrow *et al.*[11] in a series of 112 patients with gallbladder carcinoma operated on reported comparable survival patterns, i.e. 5 months for 13 patients with stage IV and 3 months for 88 patients with stage V. Compared with this series, our patients irradiated after surgery had a longer survival time, respectively 9·2 and 7·2 months.

Some authors have supported the view that radiotherapy is at least of benefit in palliation. Kopelson *et al* [5] reported a 92 per cent success rate with palliation for pain and pruritus However the number of patients discussed was too small and most also had palliative surgery procedures. In our cases the palliation effect of radiotherapy could not be evaluated because all but one of the jaundiced patients had surgical biliary drainage. The jaundiced patient who underwent only a laparotomy and biopsy remained jaundiced after radiotherapy, in spite of a reduction of tumour mass.

We encountered no adverse effects or complications after the dose of radiotherapy used. Nevertheless in order to overcome the so-called 'radioresistance' of gallbladder carcinoma, and to avoid damage by external radiotherapy caused by the increased dose in the irradiation fields, Todoroki *et al.*[8] attempted to use intraoperative radiotherapy for advanced unresectable carcinoma of the biliary tract. A single dose of 2500–3000 rad was delivered after non-curative resection in five patients[8] One was alive after 5 months while the mean survival time for the others was 11·8 months. However in this series half of the patients had a papillary adenocarcinoma, a histological finding which is usually believed to carry better prognosis[11,12].

The only randomized study of chemotherapy was published by the Eastern Cooperative Oncology Group who used such chemotherapy for patients with inoperable gallbladder cancer without showing a significant survival difference between the three chemotherapy regimens evaluated[13] The number of patients treated by radiotherapy and chemotherapy is too small to evaluate the benefit of this association[14].

We conclude that after surgery with the intent of curing gallbladder cancer, the prognosis still remains poor and future study of the use of radiotherapy will be needed to assess the benefit of this adjuvant therapy. In contrast, after palliative surgery, our experience suggests that adjuvant radiotherapy may be associated with increased survival.

Long-term follow-up after choledochojejunostomy for bile duct stones with complex clearance of the bile duct

D. J. Gouma, J. Konsten, P. B. Soeters, M. Von Meyenfeldt and H. Obertop

Department of Surgery, University Hospital Maastricht, 6201 BX Maastricht, The Netherlands

Correspondence to:
Dr D. J. Gouma

In this retrospective study, the long-term follow-up of patients undergoing choledochojejunostomy (Roux-en-Y) for bile duct stones with complex clearance of the bile duct is evaluated. Bile duct exploration and subsequent choledochojejunostomy (Roux-en-Y) was performed in 43 patients (median age 67 years) in the period 1976–82. There was no mortality and only one patient had a major complication. Twenty patients died during follow-up (median follow-up period 5 years); the median follow-up period for the remaining 23 patients was 8 years. Good long-term results were found in 98 per cent of cases. No signs or symptoms could be related to bile duct obstruction or to cholangitis. Nearly all liver function tests and serum bilirubin levels were normal in the 21 patients who were tested. We conclude that patients with bile duct stones with complex clearance of the bile duct can be safely treated by means of a choledochoenterostomy (in this study a choledochojejunostomy Roux-en-Y).

Keywords: Bile duct stones, choledochojejunostomy, sphincterotomy, biliary drainage

The management of patients with common bile duct stones has changed during the last 10 years after wide acceptance of endoscopic sphincterotomy[1]. Initially this procedure was used only for retained stones[2,3], for high risk patients, and for patients with acute cholangitis[4]. Some authors consider that endoscopic sphincterotomy is the treatment of choice for all patients with common bile duct stones, regardless of the presence of the gallbladder[5–7], believing that the results are more favourable than those for surgery[7].

Nevertheless most patients with cholelithiasis and bile duct stones are still treated surgically by means of cholecystectomy and common bile duct exploration. In 9–12 per cent of these patients bile duct stones are associated with complex clearance of the common duct, indicating that recurrent or retained stones can be expected[8,9]. In these patients internal drainage of the common bile duct can be performed by means of a sphincterotomy or sphincteroplasty, choledochoduodenostomy or choledochojejunostomy[8–10].

With the wide availability of endoscopic sphincterotomy, it has been suggested recently by some endoscopists that 'only simple cholecystectomy should be performed and surgeons should stop worrying about whether stones remain in the bile duct because endoscopic sphincterotomy can simply remove them later'[11]. When drainage is indicated, such endoscopists consider that endoscopic sphincterotomy should be preferred to operative internal drainage because this procedure has been reported to be associated with a lower morbidity and mortality[7,11]. As Johnson and Hosking have described, this approach is leading to the philosophy that 'any procedure is justified if it avoids an operation'[1].

Long-term follow-up data are now available in patients who have undergone endoscopic sphincterotomy, but detailed data drawn from series with follow-up periods of 5 years and a high percentage of follow-up (>90 per cent) are limited. The superiority of the endoscopic approach over surgical choledochoenterostomy, especially in the context of long-term follow-up, has yet to be proved.

Before the availability of endoscopic sphincterotomy, choledochojejunostomy was performed routinely in our hospital in all patients with bile duct stones where complex clearance of the bile duct was thought to justify internal biliary drainage. The present retrospective study evaluates morbidity and mortality of choledochojejunostomy, especially the long-term results.

Patients and methods

In the period 1976–82, 43 patients (21 men and 22 women) drawn from a total of 1380 patients operated on for biliary stones (1016 patients undergoing simple cholecystectomy, 323 patients having cholecystectomy and common bile duct exploration, and 41 patients with only common bile duct exploration) had complex bile duct stones found during common duct exploration (see below); all 43 patients underwent a choledochojejunostomy using a Roux-en-Y loop 60 cm long. Patients operated on after 1982 were excluded from the study to ensure a minimal follow-up period of 5 years.

Patients in whom choledochojejunostomy was performed for other benign conditions were excluded. Choledochojejunostomy was preferred to choledochoduodenostomy because the latter procedure was believed to be associated more frequently with cholangitis caused by retention of food debris in the common bile duct

The median age of the 43 patients was 67 years (range 43–87 years) and 21 patients (49 per cent) were over 70 years of age Previous biliary tract surgery had been performed in 12 patients (simple cholecystectomy in six, cholecystectomy with common duct exploration in five, and cholecystectomy and transduodenal sphincterotomy in one patient) Gastric resection for peptic ulcer had been performed previously in six patients. The preoperative findings are summarized in *Table 1*

At laparotomy all patients underwent common bile duct exploration because of bile duct stones Thirty-seven patients had multiple bile duct stones with or without sludge and gravel, impacted stones, intrahepatic stones and/or cholangitis (*Table 2*). Six patients had a solitary bile duct stone which was impacted in the lower end of the common duct or associated with stenosis or sludge. The indication for internal drainage was based on these findings and on doubt about whether total clearance of the duct could be achieved Stones impacted in the distal bile duct could not always be removed

Data regarding postoperative complications and mortality were drawn from the case records of the patients

Follow-up

The follow-up study was performed in collaboration with the patients' general practitioners, who filled out questionnaires that were sent to

them. Patients who were alive were visited by a nurse who collected blood samples for liver function tests. Data were available from all patients Special attention was paid to signs and symptoms related to cholangitis and/or the so-called 'sump' syndrome (i e. abdominal pain, jaundice and pyrexia) The cause of death of patients who died during the follow-up period was documented and, if available, autopsy findings were recorded. Liver function tests and serum bilirubin concentrations were determined in all but two of the patients alive at the time of the study.

Results

Choledochojejunostomy (Roux-en-Y) was performed in all patients, without technical problems One patient suffered from a major complication (gastric bleeding) postoperatively. A second patient had bile leakage from the Winslow drain that could be managed conservatively Six patients (14 per cent) had a wound infection, two of them leading to dehiscence of the wound. Surgical drainage had to be performed in one patient for an infected haematoma. Four of the six patients with infective complications had suffered from cholangitis before operation. Cardiopulmonary complications and urinary tract infection each developed in six patients (28 per cent) but were managed without difficulty. There was no mortality in this series. The median overall hospital stay and the median postoperative hospital stay were 23 and 13 days respectively

Twenty patients died during follow-up. The median follow-up period for these 20 patients was 5 years (range 2–9 years) Seventeen of the 20 patients had no signs or symptoms before their death that could be related to the previous biliary drainage operation nor was their death related to the operation. Of the remaining three patients, one complained of heartburn and died 9 years after the initial biliary drainage procedure from disseminated breast cancer. At autopsy no ulcer, gastritis or sign of biliary disease was found. The second patient developed a duodenal ulcer 8 years after surgery during treatment with salicylates; liver function tests were normal at that time. She died from colonic cancer 1 year later The third patient developed jaundice, probably due to the use of methyldopa: she died 2 years after surgery and, at autopsy, a patent anastomosis without any sign of obstruction or infection in the biliary tract was found. Thus, of this group of 20 patients, six died from malignancy, three from cerebrovascular disease, two from cardiovascular disease, one from pneumonia, and one from haemolytic anaemia None of the remaining seven patients who died had any sign of biliary disease or sepsis related to the previous drainage procedure.

Twenty-three patients were alive at the time of study The median follow-up period was 8 years (range 5–11 years). No patient had upper abdominal complaints at the time of follow-up and no patient was treated by his general practitioner during the entire period for signs or symptoms related to bile duct stones, stenosis and/or cholangitis. Liver function tests and serum bilirubin concentration in these patients are summarized in *Table 3* The median values were within normal limits although one patient had an isolated increase in alkaline phosphatase concentration. Two patients had an increased γ-glutamyl transferase level, one of whom also had an increased glutamic–pyruvic transaminase concentration. One patient had a borderline bilirubin level.

Discussion

Patients in this study underwent choledochojejunostomy (Roux-en-Y) for bile duct stones with complex clearance of the bile duct before endoscopic sphincterotomy became available, so that elderly patients and those with relatively high operative risk were included Choledochojejunostomy (Roux-en-Y) was performed as a routine when the risk of retained or recurrent stones was present, and no patient was excluded from the study

It still remains difficult to compare the results of this unselected series with those from recent series of patients dealt with by endoscopic sphincterotomy. Endoscopic sphincterotomy is successful in about 90–95 per cent of patients, and in about 85 per cent bile duct clearance is achieved[1,4,6,7,11,12]. Morbidity and mortality rates of this procedure are generally reported to be 2–13 per cent and 0–2 per cent respectively[1,5,7,11]. However, in a selected series of patients unfit for surgery (42 per cent aged over 80 years) Davidson *et al*[13] reported an in-hospital mortality rate of 11·3 per cent. Long-term follow-up results are now available but follow-up is usually relatively short (mean 2–3 years) and incomplete[7,14,15]. Recurrent stones and/or stenoses have been reported in 4–10 per cent of cases[1,2,7,15], although recently a series has been reported in which 21 per cent of patients developed recurrent stones[14]

In the present series internal biliary drainage was achieved in all patients without mortality. Major complications occurred in 2 per cent, and wound infection and other minor complications were reported in 14 and 28 per cent of the patients respectively. Good results after choledochoduodenostomy and choledochojejunostomy have also been reported by others[8,16–18]. Mortality rates of between 0 and 3 per cent have been reported, and the complication rates have varied from 10 to 40 per cent[8,16–18]. Transduodenal sphincterotomy and sphincteroplasty are probably associated with a higher incidence of morbidity (especially pancreatitis) and a mortality rate of up to 4 per cent[16,19]. Mortality rates after simple cholecystectomy and common bile duct exploration are reported to be between 0·5 and 3·0 per cent for patients between 60 and 70 years of age[1,20–22]. Therefore, internal biliary drainage does not seem to increase mortality greatly in most series.

Table 3 *Liver function tests and serum bilirubin concentrations of 21 patients with a choledochojejunostomy who were alive at the time of the follow-up study*

	Median	Range	Elevated values	Normal level
Alkaline phosphatase	90	36–233	233	< 125 units/l
γ-Glutamyl transferase	21	7–94	94, 77	< 50 units/l
Glutamic–pyruvic transaminase	18	10–64	64	< 40 units/l
Bilirubin	9	6–17	17	< 15 μmol/l

Long-term follow-up revealed good results in 98 per cent of the patients in our series. No patient had signs or symptoms of biliary obstruction or infection, recurrent stones or stenosis of the common bile duct. Surviving patients had liver function tests which make the prospect of cholangitis very unlikely despite a few isolated increased values Follow-up studies after choledochoduodenostomy have also shown good results but the incidence of postoperative cholangitis has varied between 2 and 4 per cent[8–10]. The presumed lower incidence of cholangitis and sump syndrome following the Roux-en-Y technique is not proved and there are no data to support the superiority of choledochojejunostomy over choledochoduodenostomy[8,10,17]. We conclude that patients with bile duct stone with complex clearance of the bile duct can be safely treated by means of a choledochoenterostomy (in this study choledochojejunostomy), and long-term follow-up has shown good results and no signs or symptoms that could be associated with the drainage procedure.

Endoscopic sphincterotomy is now the procedure of choice in elderly and unfit patients and in patients who have retained stones or cholangitis. However, we still advise an internal drainage operation in younger patients undergoing surgery for cholelithiasis when common duct stones are found and where doubt exists about complete bile duct clearance (i.e. in patients with multiple small stones, sludge or gravel).

Sixteen patients in whom malignant biliary obstruction recurred after failure of cholecystojejunostomy had attempted relief of obstruction by endoscopic insertion of an endoprosthesis. This treatment was successful in 13 patients, although one required percutaneous insertion because of duodenal distortion and one required a combined percutaneous–endoscopic approach. Median survival after stenting was 3·5 months (range from 2 weeks to 16 months). Of the three treatment failures, two patients had external drainage only and one succumbed before further treatment could be attempted. There were two complications associated with the procedure (one small bile leak and one episode of cholangitis) but the 30-day mortality rate of 12·5 per cent was related to disease progression rather than the procedure. Endoscopic stent insertion may achieve further worthwhile palliation of jaundice after the failure of surgery to relieve malignant biliary obstruction.

Keywords: Pancreatic cancer, obstructive jaundice, endoprosthesis

A wide variety of surgical procedures is performed to relieve malignant low common bile duct obstruction due to pancreatic adenocarcinoma[1]. Each has well recognized advantages and disadvantages[2] Cholecystojejunostomy is probably the quickest and easiest technical procedure when the gallbladder is dilated. The appreciable incidence of early failure due to synchronous cystic duct obstruction (often due to low insertion in the bile duct (*Figure 1*)) and late failure due to either metachronous cystic and/or proximal bile duct blockage or stomal stenosis (the former being much more common), has led many surgeons to avoid the operation when possible. Choledochoenterostomy is the initial operation preferred by some[3] and it has also been the surgical procedure of choice for early or late failure of cholecystojejunal anastomoses Secondary biliary procedures, however, probably carry a lower success rate and a higher complication rate than primary procedures We report our experience over the last 3 years with 16 consecutive patients with early or late failure of cholecystojejunal anastomoses who were managed by attempted endoscopic endoprosthesis insertion as an alternative to reoperation.

Patients and methods

Sixteen consecutive patients who had had cholecystojejunostomy performed for malignant low common bile duct obstruction due to adenocarcinoma of the pancreas had attempted treatment by endoscopic endoprosthesis insertion Failed endoscopic stenting was followed where appropriate by combined percutaneous–endoscopic stenting[4]. In three patients, the original surgery failed to provide adequate biliary drainage due to unrecognized malignant cystic duct occlusion (early failure) and in 13 cases biliary obstruction had recurred after initial successful surgical drainage (late failure). Patients with late failure were only treated if ultrasonography confirmed the presence of definite duct dilatation and the absence of significant intrahepatic metastatic disease. The median and mean time since surgery in the recurrent group was 9 months (range 3–24 months) Eight patients had histological proof of malignancy and in the remainder there was strong operative, ultrasound and endoscopic retrograde cholangiopancreatographic evidence of malignancy Patient parameters were mean age 62 years (range 43–79 years), mean bilirubin concentration 329 μmol/l (range 57–611 μmol/l, normal <17 μmol/l), mean albumin concentration 32 g/l (normal 35–53 g/l), mean urea concentration 4·3 mmol/l (normal 3·0–8·0 mmol/l) and mean haemoglobin concentration 10·3 g/l No patient had air in the bile ducts on ultrasound or plain abdominal X-ray. The gallbladder, however, was shown to be air-filled by these investigations in all patients, suggesting patency of the cholecystojejunal anastomosis (*Figure 2*) All endoscopic stents were inserted using the 4·2 mm channel Olympus TJF10 (Keymed, Southend, UK) endoscope and were 10 Fr in external diameter (*Figure 2*)

Results

Stent insertion was successful in 13 patients (81 per cent) with one being placed percutaneously because of duodenal distortion and one requiring a combined percutaneous–endoscopic procedure. Of the three failures, two patients had external drainage only after failed combined procedures and one deteriorated rapidly and had only a single endoscopic attempt at treatment before death (*Figure 3*). Two complications occurred (12 per cent) These were a small intraperitoneal bile leak after a combined procedure in one patient and, in another patient, cholangitis with septicaemia which developed after failed endoscopic retrograde cholangiopancreatography and settled with intravenous antibiotics and drainage by combined procedure. The 30-day mortality rate of 12 per cent (two patients) was entirely disease-related rather than procedure-related, although one of these patients had complete failure of drainage after dye injection (no combined procedure attempt). The two patients with external drainage survived 1·5 and 2·0 months. The median survival after stenting was 3·5 months (range from 2 weeks to 16 months) with a mean of 5 months. Survival is illustrated in *Figure 3*. Three patients required stent change before death

Discussion

More than 80 per cent of pancreatic adenocarcinomas are not amenable to surgical resection because of adverse tumour (metastasis, vascular invasion) or patient (multiple medical illness, advanced age) parameters[5] Palliation of pruritus, jaundice and pain is therefore usually the aim of therapy. Many forms of surgical biliary bypass have been described. Controversy exists about their relative merits and the

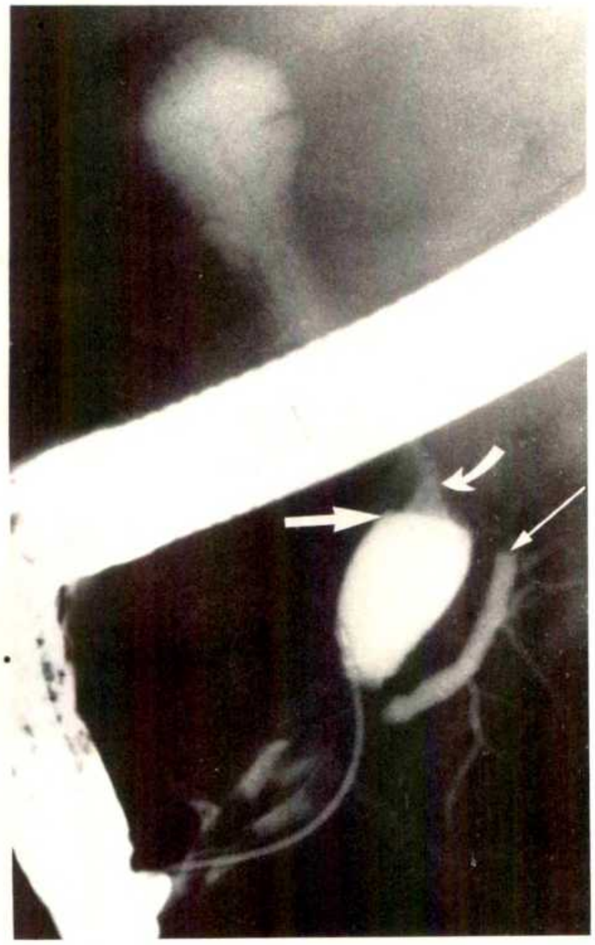

Figure 1 *Endoscopic retrograde cholangiopancreatography showing blocked pancreatic duct (thin arrow) and blocked bile duct (thick arrow) with cystic duct also occluded due to low entry into the bile duct (curved arrow)*

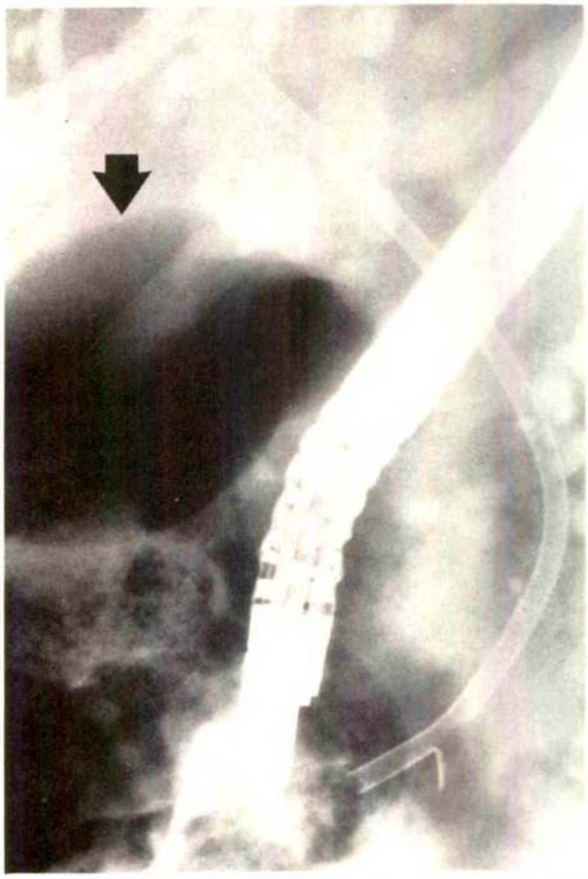

Figure 2 *Endoscopic retrograde cholangiopancreatography showing successful endoscopic stent insertion after failed cholecystojejunostomy; note air in adjacent gallbladder (arrow)*

desirability of prophylactic gastroenterostomy[6,7]. For low malignant common bile duct obstruction either the gallbladder or the common duct may be used for anastomosis. The two commonest operations performed are choledochojejunostomy and cholecystojejunostomy, although side-to-side choledochoduodenostomy is our own preference. Choledochojejunostomy often involves the formation of a Roux-en-Y loop and thus two anastomoses. The only important, though uncommon, late problem is anastomotic stricturing, which is not amenable to later endoscopic manipulation but can be managed by percutaneous transhepatic therapy. If the gallbladder is dilated, cholecystojejunostomy is possible and is undoubtedly technically simpler to perform than choledochoenterostomy. However, gallbladder dilatation does not definitely indicate cystic duct patency above the obstruction. Cholecystojejunostomy is limited by early and late cystic duct occlusion rather than anastomotic stenosis. Low cystic duct insertion predisposes to cystic duct blockage and may be deduced from plain X-ray or ultrasonography if air is present in the gallbladder but not in the biliary tree. However, as the biliary anatomy is basically unaltered, endoscopic intervention is still possible.

Internal biliary stenting has been possible by the percutaneous transhepatic route since 1978[8] and by the endoscopic route since 1980[9]. Randomized studies have suggested that drainage success rates and 30-day mortality rates are similar with surgery, percutaneous stenting or endoscopic stenting but that endoscopic stenting carries the least procedure-related morbidity[10-12]. As endoscopic stenting, if available, is a reasonable alternative to surgical palliation in fit patients and is probably the definite treatment of choice in unfit patients[13], a strong argument can be made for preferring

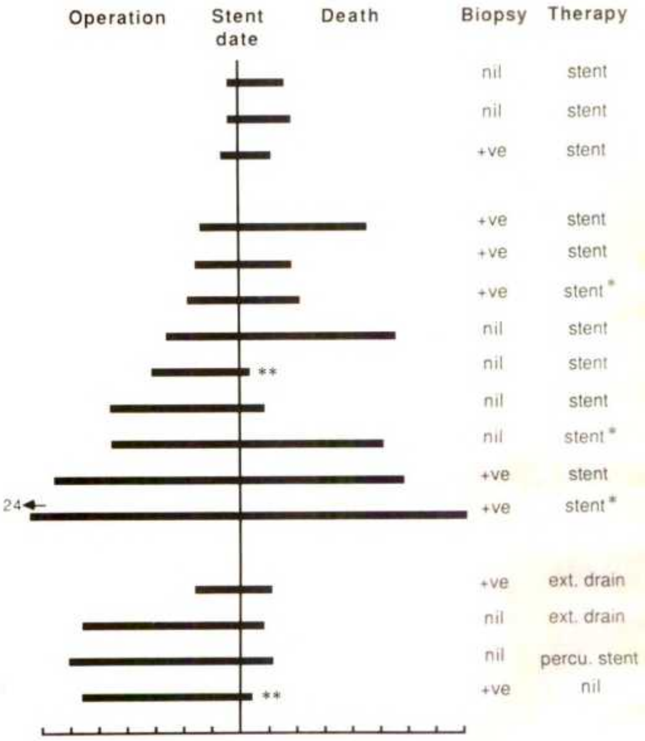

Figure 3 *Diagram of survival before and after stenting with details of histological confirmation and therapy achieved. The time before stenting is measured from the date of cholecystojejunostomy (operation) and the patients are divided into three groups: early failure, late failure with successful endoscopic stenting, and late failure with failed endoscopic stenting. * Stent change; ** died within 30 days*

endoscopic stenting to reoperation after failure of surgical biliary drainage when the bile duct is still accessible endoscopically. This review has shown that endoscopic stenting in this situation is safe and effective with a worthwhile median postprocedural survival time of 3·5 months.

Endoscopic stenting is a safe, successful alternative to reoperation for early or late failure after cholecystojejunostomy for malignant low common bile duct obstruction due to pancreatic carcinoma and should be offered as soon as surgical failure is recognized. Late failure is not necessarily a preterminal event and a further valuable period of jaundice-free survival may be obtained.

Mr A. Murray

The use of a pulsed dye laser to fragment human gallstones is reported. Laser energy was delivered by a 320 μm quartz fibre at wavelengths of 440, 480, 504, 560, 590, and 635 nm, in 1 μs pulses at energies of 5–60 mJ per pulse, producing peak powers of the order of 10^5 W. Cholesterol, pigment and mixed stones were fragmented. The shorter wavelengths were most efficient, using significantly less energy at 440 and 480 nm than at the longer wavelengths. Pigment stones were fragmented with significantly less energy than those in which cholesterol predominated. Thermal imaging during laser treatment showed no significant rise in temperature in the bulk of the stone. Absorption spectroscopy of bile revealed a peak at 450 nm, coinciding with the known absorption characteristic of bilirubin. Bile strongly attenuated light at shorter wavelengths, even at dilutions as great as 1:20 and protected samples of biliary epithelium from laser damage except when the optical fibre was in direct contact. The pulsed dye laser may offer significant advantages over current methods of biliary stone fragmentation.

Keywords: Choledocholithiasis, lithotripsy, laser surgery

Endoscopic sphincterotomy and stone extraction is successful in up to 90 per cent of patients with common duct stones, but fails if the stones are too large to pass through the sphincterotomy. In these cases there are several techniques being developed to fragment the stone before its removal. Mechanical lithotripsy, using a basket to crush the stone *in situ*, is relatively cumbersome and more complex methods such as ultrasonic, electrohydraulic and laser lithotripsy are being adapted from experience gained in treating stones within the renal tract[1,2]. Extracorporeal lithotripsy is being assessed for the fragmentation of gallbladder and common duct stones, but the indications and limitations are not yet clear and the devices are not widely available.

There are three types of laser in regular use in various fields of medicine: the argon, neodymium YAG and carbon dioxide devices. Each produces a continuous laser beam of a specific wavelength that achieves its effect by heating the target tissue. A purely thermal mechanism, however, will not fragment gallstones. Teng *et al.*[3] have shown that by pulsing laser energy in short, high energy bursts an 'acoustic' shock-wave effect is produced that can effectively fragment stones. Lux *et al.*[4] reported the first successful endoscopic retrograde laser lithotripsy in man in 1986 and have recently published a total of eight further cases[5]. They used a *pulsed* neodymium YAG laser which produces light in the near infrared part of the spectrum (1064 nm). Light at this wavelength has a low absorption:scattering ratio which results in poor absorption and high penetration through tissues. As biliary stones have a variable bile pigment content it may be possible to take advantage of enhanced absorption of light at shorter wavelengths by these pigments and thus reduce the energy necessary for fragmentation and thereby increase the safety margin.

Biliary stones are a heterogeneous group, varying in cholesterol, bile pigment and calcium salt content. They lie in an area of delicate anatomy in which thermal or mechanical damage to the biliary structures must be avoided and the margin for error during therapeutic manoeuvres is small. It is therefore imperative, if using a laser within the biliary tree, to choose the most efficient device in terms of wavelength, fragmentation energy and safety.

We report *in vitro* experiments of gallstone fragmentation and bile absorption using a pulsed dye laser at six wavelengths across the visible spectrum, to determine the most efficient and safe laser parameters.

Materials and methods

Stone fragmentation

A total of 55 biliary calculi were collected from ten patients each having five or more stones. The stones were weighed, their maximum diameter measured with an engineering micrometer and they were then stored dry, in sealed containers. The stones from each patient were randomly allocated one to each of six groups. Two groups contained ten stones, three groups had nine and one had eight.

Pulses of laser energy, each of 1 μs duration, were generated by a xenon flashlamp-pumped pulsed dye laser (Model MDL-1P, Candela Laser Corporation, Wayland, Massachusetts, USA). Six wavelengths were produced sequentially using 2×10^{-4} M solutions of six organic laser dyes: coumarin (440, 480, and 504 nm), rhodamine (560 and 590 nm) and DCM (635 nm) (Exciton, Dayton, Ohio, USA). Each group of stones was subjected to laser energy at one of the above wavelengths. The energy was conducted to each stone by a 1·5 m length of a 320-μm core, step-index flexible optical fibre. This was held in direct contact with the stone by a counterbalanced arm weighted to 10 g. Each stone was supported in turn on a gelatin mould within a polythene flask and immersed under 1 cm of saline. Energy was delivered as a series of 1 μs pulses at a rate of 10 pulses per second. The initial pulse energy was 5 mJ, increasing by increments of 5 and then 10 mJ every 100 pulses, up to a maximum of 60 mJ per pulse. This resulted in an energy density (energy per unit area) at the fibre tip of 6·75–75 J cm^{-2} and a peak pulse power of the order of 10^5 W. The total energy at which gross fragmentation occurred was recorded. The average power output was monitored before and after the delivery of each energy increment by a Coherent 210 power meter (Coherent, Palo Alto, California, USA).

Stone analysis

Quantitative stone analysis was performed on the fragments resulting from lithotripsy. After grinding to a powder, the cholesterol fraction was extracted with ether. The calcium salts were extracted by passage through concentrated hydrochloric acid, leaving a residue composed of bile pigments. The dry sample weight was measured at each stage.

Absorption spectroscopy of bile

Six samples of bile were collected from patients undergoing cholecystectomy. After storage at 4°C for up to 48 h, a 4-ml portion of each sample was subjected to absorption spectroscopy between 350 and 1100 nm, with a Shimadzu UV 160 spectrophotometer (Shimadzu Corporation, Duisberg, DDR). This determined the typical absorption

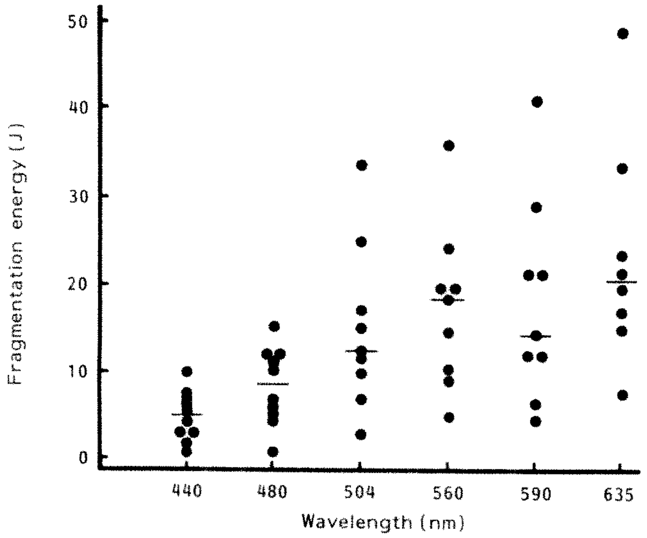

Figure 1 *Fragmentation energy at six wavelengths for each of 55 gallstones. The total energy (J) to fragment each stone is plotted against wavelength (nm)*

characteristics over the whole range of the visible spectrum and, in particular, at those wavelengths used in these experiments.

Attenuation of laser light by bile

To investigate the attenuation of laser light at varying bile concentrations, further 4-ml samples were diluted with known volumes of normal saline. Aliquots of 1 cm^3 were held in a 1 cm^2 polished glass cuvette, the base of which was placed on a glass coverslip in contact with the sensing face of the power meter. Laser energy, at a wavelength of 480 nm, was conducted to the sample by a 320 μm diameter flexible optical fibre held in a micromanipulator. The power transmission was measured at bile dilutions of 1:10, 1:20, 1:40 and 1:100, at pulse energies of 20–100 mJ, in 20-mJ increments.

Tissue damage and the effect of bile

Human gallbladder and bile duct specimens were obtained from fresh cadavers. The tissues were then cut into 1 cm^2 samples and exposed to laser energy conducted by the 320 μm optical fibre held in a micromanipulator at distances of 1, 2, 3, 4 and 5 mm from the epithelial surface. Exposures of 100 pulses were then made at pulse energies of 20, 40, 60, 80 and 100 mJ, with the samples immersed both in saline alone or known dilutions of bile. Each specimen was snap-frozen and sectioned in a cryotome. The depth of any crater resulting from ablation by the absorption of the laser energy was measured with optical micrometry. A proportion of sections were stained with haematoxylin and eosin and then examined under light microscopy for signs of thermal damage.

Thermography

To document the temperature changes in stones undergoing fragmentation, high resolution thermographic images were recorded using a Thermovision 870 infrared camera system (Agema, Leighton Buzzard, UK). The camera was focused on the fibre–stone interface in air. The laser was fired at a range of energies from 20 to 60 mJ to produce stone fragmentation. The resulting infrared image was recorded digitally to enable an accurate estimation of the surface temperature of the bulk of the stone adjacent to the point of fragmentation.

Results

Stone fragmentation

The 55 stones subjected to laser lithotripsy were of median weight 2·1 g (range 0·5–3·5 g) and median maximum diameter 1·6 cm (range 0·7–2·1 cm). In all, ten stones were fragmented at a wavelength of 440 and ten at 480 nm, nine stones were fragmented at 504 nm, nine at 560 nm, nine at 590 nm and eight at 635 nm. There were no significant differences in the weights of the stones between groups. Fragmentation was achieved with a wide range of energy, from a threshold energy of 20 mJ per pulse for predominantly pigment stones at the 440 nm wavelength, to energies of 60 mJ at the longer wavelengths.

Typically the fibre drilled into the stone at sub-fragmentation energy after which gross fragmentation was achieved at the next energy increment. The resulting fragments were of varying size, usually comprising two or more large fragments with multiple small particles. The median maximum diameter of the largest fragment from each stone was 0·81 cm (range 0·45–1·05 cm). During fragmentation, a 'cracking' sound was audible with each laser pulse over 20 mJ in energy. The total fragmentation energy for each stone at each wavelength is plotted in *Figure 1*. As the wavelength was increased, the energy necessary to achieve fragmentation also increased. When compared with the fragmentation at 440 nm, the energies required were significantly greater at 504 nm ($P<0·05$) and at 560, 590 and 635 nm ($P<0·01$). At 480 nm the energy was significantly less than at 560, 590 and 635 nm ($P<0·01$, Wilcoxon rank sum). Fragmentation was most efficient therefore at the shorter wavelengths. No macroscopic damage to the delivery fibre was observed during the fragmentation, although microscopic examination showed roughening of the previously cleaved surface suggestive of local mechanical trauma.

Stone analysis

Stone analysis revealed a cholesterol content of 22–93 per cent, a bile pigment content of 2–62 per cent and calcium salt content of 4–16 per cent. Fragmentation energy varied with stone composition. Stones composed largely of bile pigment were fragmented with a median energy of 2·2 J (range 0·7–6·5), which was significantly less energy than the median of 24·2 J (range 10·4–71 J) required to break stones composed predominantly of cholesterol ($P<0·01$, Wilcoxon rank sum).

Absorption spectroscopy of bile

Bile spectroscopy typically revealed a biphasic absorption maximum between 300 and 500 nm (*Figure 2*), the second peak coinciding with the peak absorption of bilirubin at 453 nm. Ascending through the visible spectrum the absorption decreased rapidly above 500 nm reaching a minimum in the infrared.

Attenuation of laser light by bile

Bile was found to strongly attenuate laser energy at the shorter wavelengths. The attenuation at 480 nm by known dilutions of six samples of bile are plotted in *Figure 3*. Complete absorption of energy was found with dilutions up to 1:10 in all samples. At dilutions greater than 1:10 there was measurable absorption even in dilutions as great as 1:100.

Tissue damage and the effect of bile

Craters discernible to the naked eye were created at all laser energies when the optical fibre was held in contact with each

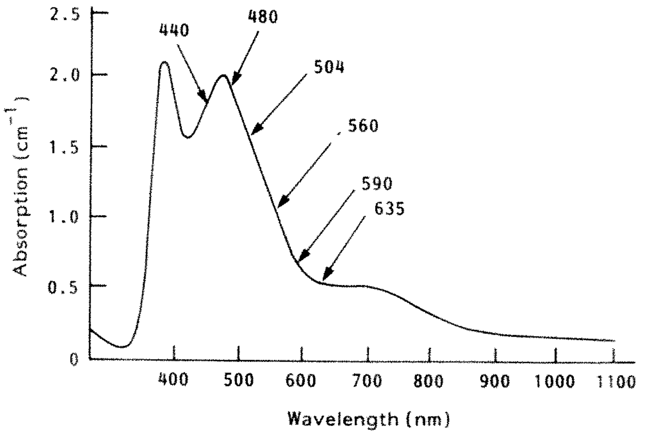

Figure 2 *Typical absorption spectrum of human bile with lithotripsy wavelengths superimposed. The absorption (cm^{-1}) is plotted against wavelength (nm)*

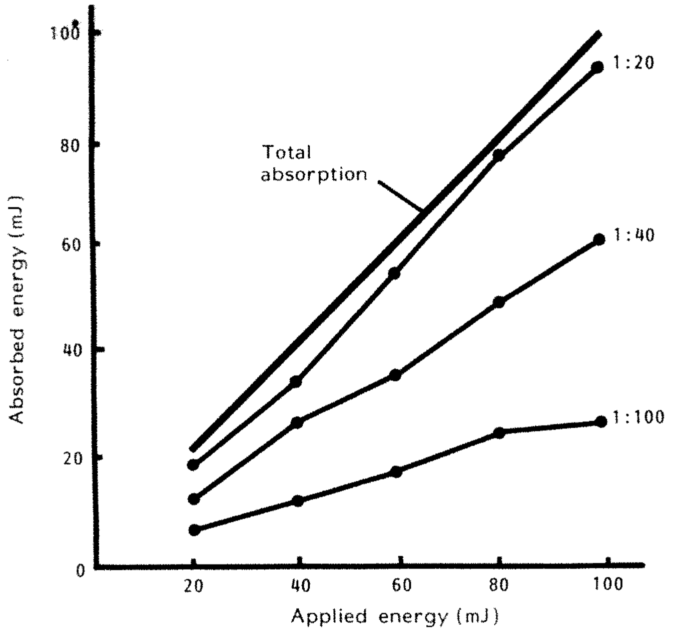

Figure 3 *Attenuation of 480 nm laser energy by bile dilutions of 1:20, 1:40 and 1:100. Each point represents the median of absorbed energy of six samples of human bile and is plotted against incident pulse energies of 20, 40, 60, 80 and 100 mJ*

specimen. The diameter of the craters matched that of the fibre. On light microscopy the lesions had a well defined edge, without signs of burning or charring and with no surrounding zone of thermal coagulation. All these features are consistent with the effects known to be produced by pulsed lasers. Craters also occurred when the fibre was held under saline, at up to 3 mm distance from the epithelium at energies above 40 mJ per pulse. Crater depth, as measured by optical micrometry, increased with duration of exposure and pulse energy. When immersed in undiluted bile, craters occurred only when the fibre was in contact with the epithelium, thus effectively excluding bile from the interface. With the fibre held at 1 mm distance from the epithelium, craters were only produced at pulse energies of 20 mJ and above, and at bile dilutions of more than 1:10. At greater distances, even in very dilute bile, the beam divergence and absorption led to a power density that was insufficient to produce discernible craters.

Thermography

Thermographic imaging confirmed that the bulk of the stone does not undergo a measurable temperature rise during laser fragmentation, even when supramaximal energies of 100 mJ were used in air. A rise of between 10 and 20°C was recorded immediately adjacent to the point of fibre-penetration of three stones tested. The remainder of the surface of the stone showed no temperature rise up to and beyond the moment of fragmentation.

Discussion

This study confirms that human gallstones can be reliably fragmented by laser energy from a pulsed dye laser at a range of wavelengths across the visible spectrum.

Simple modifications of current methods of basket extraction, with a central channel in the catheter for the optical fibre, will allow this contact technique to be applied *in vivo*.

Burhenne heralded the non-surgical management of common duct stones when, via a T tube track, he fragmented a common duct stone with an electrohydraulic probe[6] and went on to treat many hundreds of patients with the aid of this technique[7]. The use of laser energy within the bile duct is a natural progression from this work. The ability to couple laser energy to fine flexible optical fibres of a diameter of <0·5 mm is ideally suited to an endoscopic approach and compares very favourably with the probe diameters of up to 3 mm for current electrohydraulic methods.

Lux *et al.* have reported *in vitro* work on lithotripsy using a neodymium YAG laser which produces a pulse of relatively long duration (0·1–10 ms) at a wavelength of 1064 nm. They report a median fragmentation energy of 32 J for stones < 1·5 cm in diameter, and 80 J for those > 1·5 cm. The energies necessary for fragmentation of comparable stones with the pulsed dye laser at short wavelengths are of the order of 6–10 times less.

Pulsed laser energy has to be applied directly to the stone surface for a reliable effect to be achieved. Fragmentation required significantly less energy at the shorter wavelengths (440–480 nm) than at the longer (504, 560, 590 and 635 nm). At 440 nm the median fragmentation energy was four times less than that required at the longest wavelength (635 nm). Stone particles resulting from fragmentation tended to be of a relatively large size and would in some cases need further fragmentation before successful extraction. Predominantly pigment stones required significantly less energy for fragmentation than those of a mixed or largely cholesterol content ($P < 0{\cdot}01$). It is the bilirubin content of gallstones that leads to their more efficient fragmentation at shorter wavelengths. There are few published data on light absorption by gallstones. Leung *et al.*[8] have shown that at 700 nm the absorption coefficients of cholesterol and pigment stones are 30 and 100 cm^{-1}, such that pigment stones, being more highly absorptive, would fragment at lower energies. The results in this paper would suggest that the differential absorption between predominantly cholesterol or pigment stones holds good across the spectrum. Cholesterol stones are still effectively broken up by the pulsed dye laser, as the acoustic shockwave production is a function of the high peak power of the pulse, which is then further augmented in the pigment-containing stones. The short pulse length of the pulsed dye laser (1 μs) as compared with the YAG device (10^2–10^3 μs) produces a higher peak power for a given pulse energy and thus an improved fragmentation efficiency. The YAG laser is therefore less than ideal for the production of the optimal conditions for lithotripsy.

The exact mechanism of action of pulsed lasers in stone fragmentation is still under debate, but it appears that above a certain threshold the high peak energy concentrated on a very small area of the stone surface results in the instantaneous production of a plasma of ionized molecules lasting for a fraction of a second. The expansion of this plasma then produces stress waves that propagate through the stone, resulting in cleavage at planes of structural weakness. This process would account for the necessity for contact between the fibre and the stone for effective fragmentation to be achieved. The audible 'crack' is thought to result from the plasma production. Shorter wavelengths are more efficient as they are better absorbed by the stone constituents and thus lower the energy requirements for the production of plasma formation. Stone fragmentation is more effective under fluid as this compresses the shockwave in the direction of the stone. Spectroscopy of samples of human bile revealed a peak centred on the maximum absorption of bilirubin at 453 nm. Bile around a stone will strongly absorb any stray laser light, thus decreasing the risk of laser-induced damage to the bile duct. We have shown that even when greatly diluted, as would be the case when contrast media are injected into the duct to facilitate control, bile will effectively absorb laser energy. At a dilution of 1:20, a 1 cm depth (equivalent to a depth of neat bile of 0·5 mm), laser energy at up to 100 mJ, at the 480 nm wavelength, is 95 per cent absorbed and this degree of protection avoids laser damage to biliary epithelium *in vitro*.

Thermal imaging has confirmed that there is an insignificant temperature rise of the stone even when fragmented at high energies in a thermally insulating air medium. Infrared imaging is only capable of defining surface temperature and cannot measure temperatures deep within the stone. However, there are sound physical arguments against there being a significant thermal rise, because of the particular pulse parameters used. Because the pulse duration of 1 μs is very short when compared with the period between pulses (100 ms at a pulse repetition rate of 10 Hz), any heat produced with each laser pulse has time (the characteristic thermal relaxation time) to dissipate before the next pulse arrives. Thus there is no significant relentless rise in temperature during laser treatment which would be found if a continuous wave laser was used. This has important implications for avoiding thermal damage to surrounding biliary structures during *in vivo* laser treatment.

Pulsed dye laser energy will damage biliary epithelium if the fibre is held in direct contact while firing for many seconds, but this is unlikely to occur when the laser fibre is in contact with the stone in a bile medium. If a lesion is produced in the duct wall, there is no thermal damage to the surrounding tissues because of the short-pulsed nature of the energy.

To elucidate the pathogenesis of renal insufficiency associated with obstructive jaundice we have studied spontaneous water intake and body water compartments in rabbits undergoing common bile duct ligation. Total body water, extracellular water and plasma volume were measured by multi-isotope dilution technique. During the initial 6 postoperative days spontaneous water intake was 898 ml in sham operated animals (SO) but only 280 ml in jaundiced rabbits (OJ6) (P < 0·01). *Creatinine clearance was almost unchanged in SO but fell to 60 per cent of the preoperative values both in OJ6 and in paired-drink sham operated animals (SO2). There was a 15 per cent decrease in total body water* (P < 0·01) *and a 24 per cent decrease in extracellular water* (P < 0·01) *6 days after bile duct ligation. There was a further reduction of the extracellular water to 35 per cent and a 15 per cent reduction of plasma volume 12 days after ligation. Water restriction mimicked the alterations in body composition produced by bile duct ligation. We conclude that bile duct ligation is associated with hypodypsia and a depletion of extracellular water and plasma volume. These alterations could explain the tendency to develop hypotension and renal failure which are associated with obstructive jaundice.*

Keywords: Obstructive jaundice, renal failure, fluid compartments

Although several measures have been proposed to prevent postoperative renal failure in obstructive jaundice up to now none has gained widespread acceptance. Recently published randomized clinical trials have failed to confirm the value of mannitol[1] or oral administration of bile salts[2] in preventing renal function deterioration in this setting. Newer methods are also likely to fail since the pathogenesis of renal failure in obstructive jaundice has not been clearly elucidated. Several observations have indirectly shown that water depletion may play a fundamental part[1–6]. However, no studies have been carried out to measure directly the water balance and fluid compartments in obstructive jaundice. Accordingly in the present article we report studies of water intake, renal function and body composition in rabbits undergoing ligation of the common bile duct aiming at disclosing changes in body water compartments induced by biliary obstruction.

Materials and methods

California male rabbits with a mean weight of 2700 g (range 2490–3000 g) were used in all experiments. To allow for adaptation the animals were kept in metabolic cages on arrival from 7 days before the study to its end. The experiment was carried out in two phases. First, water balance and renal function were determined before and 6 days after surgery in three groups of rabbits: sham operated (group SO, $n = 8$), common bile duct ligated (OJ6, $n = 8$) and a sham operated group that was offered the same amount of water and chow as that drunk and eaten by jaundiced rabbits (group SO2, $n = 8$). Diuresis and water intake were recorded daily. Urine and plasma osmolarity were determined on day 6. Creatinine clearance was measured using standard techniques.

In a second phase, body composition studies were carried out in four different groups of animals. In group SO ($n = 7$) body composition was assessed before and 6 days after a sham operation, in group OJ6 ($n = 8$) body composition was assessed before and 6 days after bile duct ligation, in group OJ12 ($n = 6$) body composition was assessed before and 12 days after ligation and, finally, in group SO2 ($n = 8$) body composition studies were carried out before and after a sham operation after which animals were paired-drunk and paired-fed with OJ6 rabbits.

Double ligation of the common bile duct was performed through a midline incision under general anaesthesia with ketamine (10 mg/kg) and diazepam (2 mg/kg) intramuscularly and halothane (1–3 per cent). In sham operated animals a midline incision, under the same type of general anaesthesia, was also performed and the common bile duct was dissected free but not ligated. Thus, the duration and visceral handling in sham operated animals was very similar to that of animals undergoing bile duct ligation. Cefonicid (125 mg) was administered intramuscularly 1 h before surgery and 24 h and 48 h after the intervention. At the end of the experiment, animals were killed and autopsies performed. In all animals the state of the common bile duct was assessed, particularly in animals belonging to groups OJ6 or OJ12 in which dilatation of the ligated bile duct was confirmed.

The weight of the rabbits was determined daily and the mean of three repeated measurements was recorded. For the determination of total body water, extracellular water and plasma volume the following three solutions were prepared: 740 kBq/ml $^{3}H_2O$ (Ire Medgenix, Belgium), 740 kBq/ml $^{35}SO_4$ and 74 kBq/ml ^{125}I-labelled albumin (Amersham International, Amersham, UK). First, 0·5 ml (370 kBq) of tritiated water and radiosulphate were injected through the marginal vein of the ear. After 3 h a 5-ml arterial blood sample was obtained and plasma was promptly separated and deproteinized by adding 10 per cent trichloroacetic acid (2 ml plasma/4 ml acid)[7]. This plasma was used to measure the ^{3}H and $^{35}SO_4$ radioactivity. Then 0·5 ml (37 kBq) ^{125}I-labelled albumin solution was injected and 10 min later another 5 ml arterial blood sample was obtained for counting the ^{125}I radioactivity. For the postoperative study the same procedure was applied but a basal serum sample was obtained to subtract the remaining radioactivity.

To determine the total radioactivity of ^{3}H and $^{35}SO_4$ administered, standard solutions of 0·5 ml of the isotope solutions in 100 ml of distilled water were prepared. Then 1 ml of these solutions was dissolved in 10 ml of deproteinized rabbit plasma obtained from rabbits with jaundice (OJ6, $n = 5$, OJ12, $n = 5$) or controls ($n = 5$) to prepare standard solutions with a similar degree of quenching to those of the serum samples. This 1/1000 solution was used for β counting. The total radioactivity of the administered ^{125}I-labelled albumin was calculated diluting 0·5 ml of the stock solution in 100 ml distilled water. All the counting procedures were carried out in triplicate. ^{3}H and $^{35}SO_4$ radioactivity was measured after dissolving the deproteinized serum samples in 13 ml scintillation liquid (Scintran,

0007–1323/89/050461–04$3.00 © 1989 Butterworth & Co (Publishers) Ltd

BDH Chemicals Ltd., Poole, UK) in a LKB 1217 Rackbeta (LKB Wallac, Turku, Finland). ^{125}I-labelled albumin radioactivity was measured in a Packard 800C (Packard, USA) counter. Body water compartments were measured using the following formulae in which we assumed a Donnan factor of 0·93 and a plasma protein concentration of 0·9 g/l. In the first two formulae, the number 3 represents a dilution coefficient:

$$\text{Total body water} = \frac{\text{d.p.m/ml } ^3H_2O \text{ (standard)} \times 1000 \times 0{\cdot}93}{\text{d.p.m./ml } ^3H_2O \text{ (plasma)} \times 3}$$

$$\text{Extracellular water} = \frac{\text{d.p.m./ml } ^{35}SO_4 \text{ (standard)} \times 1000 \times 0{\cdot}93 \times 0{\cdot}9}{\text{d.p.m./ml } ^{35}SO_4 \text{ (plasma)} \times 3}$$

$$\text{Plasma volume} = \frac{\text{c.p.m./ml } ^{125}\text{I-labelled albumin (standard)} \times 100}{\text{c.p.m./ml } ^{125}\text{I-labelled albumin (plasma)}}$$

We did not calculate the urinary excretion of the isotopes to simplify the calculations. Intracellular water and interstitial water were indirectly obtained from the measured compartments. Sizes of body water compartments are expressed in absolute numbers and as percentages of the basal values to minimize the influence of the body weight which was slightly lower in group OJ12 compared with the remaining three groups. Comparisons between groups were carried out with the analysis of variance test for grouped non-parametric samples (Kruskal–Wallis) and differences between single groups with the Mann–Whitney *U* test for unpaired data. Pearson's correlation coefficient was used to assess the relationship between different variables. Statistical significance was accepted if $P<0{\cdot}05$ when calculated for two tails.

Results

Water intake and renal function

The results are shown in *Table 1*. During the 6 days of the experiment, OJ6 rabbits drank a mean of 280 ml water whereas SO rabbits drank 898 ml ($P<0{\cdot}01$). The percentage of body weight loss was significantly higher in groups OJ and SO2. The percentage fall in creatinine clearance was similar in groups OJ6 and SO2 and was significantly greater from that of group SO ($P<0{\cdot}01$). In spite of a similarly reduced water intake, the OJ6 rabbits had a lower urine osmolarity than the water restricted animals.

SO, sham operated; OJ6, jaundiced; SO2, sham operated paired-drunk; n.s., not significant (Kruskal–Wallis non-parametric analysis of variance). By non-parametric comparison there were no differences between groups OJ6 and SO2

Body composition

The basal preoperative body composition of all groups is shown in *Table 2*. There were significant changes in body water compartments 6 days after common bile duct ligation. Weight loss was greater in OJ6 than in SO rabbits (14 *versus* 6 per cent, $P<0{\cdot}0002$). In group OJ6 weight loss closely correlated with total body water loss during the same period ($r^2=0{\cdot}82$, $P<0{\cdot}0001$, *Figure 1*). When compared with group SO, OJ6 rabbits showed a greater reduction in total body water mainly owing to a reduction of the extracellular fluid compartment (*Table 3*). When group OJ6 was compared with group OJ12, a further and significant reduction in the extracellular fluid compartment was appreciated which was associated with a 15 per cent decrease in plasma volume (*Table 4*). In spite of the depletion of the extracellular compartment, intracellular water was normal at this stage, a fact consistent with isotonic extracellular fluid loss. The paired-drunk sham operated rabbits showed alterations of body composition similar to those of rabbits undergoing bile duct ligation (*Table 5*).

Discussion

Although the histological appearance of kidneys of patients dying of acute renal failure associated with obstructive jaundice closely resembles that associated with hypovolaemic shock[8], no satisfactory explanation has been proposed to link this phenomenon with biliary obstruction and the true cause of renal dysfunction in this setting has not yet been firmly

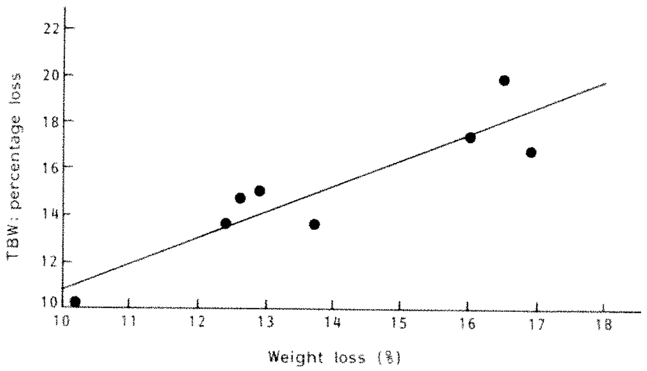

Figure 1 *Correlation between weight loss and total body water (TBW) loss in rabbits 6 days after common bile duct ligation; values are expressed as percentages of the basal preoperative measurements. y = 1·135x − 0·538, r² = 0·82, P < 0·001*

established. Several hypotheses have been developed to explain the pathogenesis of this complication. These can be broadly classified into three main lines of thought: nephrotoxicity of bile components, haemodynamic alterations and harmful effects of endotoxin. The nephrotoxicity theory holds that some substances that are usually excreted through the bile tend to accumulate in plasma when bile flow is interrupted. When excreted through the kidney these could have either a direct nephrotoxic effect or 'sensitize' the kidney to the action of other factors that can cause renal damage. Substances that have been implicated are the IgA immunoglobulins[9], bile salts[10] and conjugated bilirubin[11]. A recent review by Green *et al.*[12] summarizes the work done in the field of the 'haemodynamic alterations' theory. Briefly, cholaemia would impair left ventricular performance, diminish vascular tone and/or impair the responsiveness to sympathetic vasoconstrictor influences thus explaining the increased susceptibility to shock in obstructive jaundice.

Bailey[13] proved the presence of endotoxaemia in rats and in man during obstructive jaundice and advanced the hypothesis that this might be related to increased bowel absorption of endotoxin due to the absence of bile salts. Endotoxin would result in renal damage either by intrarenal activation of the coagulation cascade, leading to a localized intravascular coagulation, or through haemodynamic alterations. Some studies have suggested that oral administration of bile salts to prevent endotoxin absorption[14–16] or of lactulose to reduce bacterial proliferation in the bowel lumen[17] might prevent renal function deterioration in obstructive jaundice. Recently, however, a clinical randomized trial has failed to prove any benefit from the preoperative administration of ursodeoxycholic acid[2] and further studies are still required to prove the clinical usefulness of these treatments.

The aforementioned hypotheses linking renal failure and obstructive jaundice have failed to emphasize the role of water depletion which, in our view, is the final common pathway leading to impairment of renal function. Topuzlu and Stahl[18] were the first to suggest that renal impairment in obstructive jaundice could be caused by hypovolaemia after they induced a water and sodium diuresis in the dog following intravenous injection of bile. Williams *et al.*[3] demonstrated that in jaundiced dogs the amount of haemorrhage necessary to induce hypovolaemic shock was much less than in control animals. Hishida *et al.*[4] showed, in a rabbit model, that 10 days after common bile duct ligation there was evidence of secondary hyperaldosteronism. Cioffi *et al.*[6] found that the perfusion pressure of the isolated 'jaundiced kidney' in rabbits with ligated common bile ducts was superior to that of sham operated animals. We interpret all these studies as providing indirect proof of volume depletion. However, to date, no systematic studies have been carried out to investigate the body water compartments in obstructive jaundice. The only work specifically devoted to measure blood volume in obstructive jaundice was that published in 1971 by Gillet[19]. He measured plasma volume using radioiodinated albumin 8 days after common bile duct ligation in rats and was able to show that it was reduced by 15 per cent.

Using a multi-isotope dilution technique to measure body water compartments we have found that 6 days after common bile duct ligation there is a 15 per cent reduction of total body water mostly owing to depletion of the extracellular compartment. At this stage, body weight closely correlated with the degree of water loss. The plasma volume remained unaffected but did not show the physiological expansion observed in sham operated animals. Twelve days after common bile duct ligation there is a further reduction, up to 35 per cent, of the extracellular fluid compartment which then became associated with a 15 per cent decrease of plasma volume. The intracellular water remained almost unaffected throughout the period of the investigation probably because no osmotic changes occurred in the extracellular compartment.

At a later stage, 12 days after common duct ligation in our model, reduction in plasma volume ensues. This may result in reduced renal blood flow probably making the kidney more sensitive to any kind of insult. Preliminary studies in our laboratory have shown a significant reduction of renal plasma flow, assessed by para-aminohippurate clearance, as soon as 4 days after bile duct ligation.

The causes of volume depletion are to be found in a deterioration of the renal mechanisms of water and sodium preservation and in the lack of water and sodium intake. In the first phase study we found that 6 days after bile duct ligation, jaundiced animals excrete a more dilute urine than their sham operated counterparts despite being volume depleted. In unpublished observations we found that administration of saline to jaundiced animals, despite some protective effect on creatinine clearance, is followed by brisk diuresis indicating their inability to retain water and salt. Hypodypsia may also be an important factor leading to negative water balance in obstructive jaundice. Spontaneous water intake was much

Table 5 *Size of body water compartments in jaundiced rabbits and paired-drunk controls 6 days after surgery*

	OJ6 (*n* = 8)	SO2 (*n* = 6)	*P*
Total body water	1675 ± 162 (−15)	1735 ± 98 (−15)	n.s.
Intracellular water	1043 ± 139 (−8)	1005 ± 75 (−8)	n.s.
Extracellular water	632 ± 58 (−24)	730 ± 71 (−22)	n.s.
Interstitial water	549 ± 57 (−26)	637 ± 67 (−24)	n.s.
Plasma volume	94 ± 8 (−1)	88 ± 4 (−3)	n.s.

Values are mean ± s.d. expressed as millilitres of water; OJ6, jaundiced, assessed 6 days after bile duct ligation; OJ12, jaundiced, assessed 12 days after bile duct ligation; numbers in parentheses express the mean percentage decrease of each compartment in respect to its preoperative value; n.s., not significant (Mann–Whitney *U* test) lower in jaundiced than in sham operated rabbits. Furthermore, the magnitude of the body weight reduction and the fall of creatinine clearance characteristic of jaundiced animals, were mimicked in a group of sham operated rabbits offered the same amount of water as that drunk by animals after bile duct ligation. Furthermore, body composition in sham operated water-restricted controls showed the alterations observed in obstructive jaundice. This suggests that reduced water intake plays an important part in the pathogenesis of contraction of the extracellular fluid compartment.

In this setting of extracellular fluid depletion associated with marginal hypovolaemia, factors such as endotoxin, aminoglycosides, haemorrhage or hypotension of any origin may easily lead to acute renal failure. Probably there are no specific mechanisms linking jaundice and renal failure but common, well known causes of renal failure can precipitate this complication much more easily in jaundiced patients because they are previously water depleted.

Pancreatic and peripancreatic debridement combined with a closed cavity system of drainage was used to manage necrotic sequelae of severe acute pancreatitis in 14 patients. Intravenous contrast-enhanced computed tomography, or latterly incremental dynamic computed tomographic angiography, accurately detected and localized necrotic tissue. Operation was delayed where possible to permit demarcation of the necrotic area and the development of a 'capsule' of inflammatory tissue. A retrocolic route of access to the necrotic area was used in nine cases, and purpose-made silicone elastomer tubes with an outside diameter of 20 mm were positioned so that drainage was assisted by gravity when the patient was supine. The cavity was irrigated with saline (initially 2 litres daily), and in the last seven patients Trasylol® was included in the irrigation fluid (5×10^6 kallidinogenase inactivator (KI) units/litre) for the first postoperative week. Three elderly patients died (mean age 72 years) but all patients aged less than 68 years survived. Planned reoperation was carried out in two patients, but further reoperations were not required in the remaining 11. Drainage tubes were removed when contrast studies showed the cavity to be small and superficial; the median duration of drainage was 28 days. Although sinograms demonstrated fistulae between cavity and small bowel (n = 4) or small bowel and colon (n = 2), no clinical problems resulted and all closed spontaneously. Closed drainage may be as effective as techniques of marsupialization, but avoids the need for frequent relaparotomy.

Keywords: Acute pancreatitis, pancreatic necrosis, debridement, surgical drainage

Despite improvements in the management of critically ill patients, the overall mortality rate from acute pancreatitis in the UK remains about 10 per cent[1], although most attacks have a benign course and result in uncomplicated recovery. Serious complications of acute pancreatitis are frequently a consequence of necrosis of parts of the gland or adjacent tissues. Consequences of necrosis include pseudocysts in which the dominant lesion is a local collection of pancreatic juice, often producing relatively few symptoms, and abscesses in which an infected collection develops. In many of the most severely ill patients, extensive areas of the pancreas and/or peripancreatic tissues become necrotic, with a relatively small fluid component but with widespread oedema of adjacent tissues and organs. Infection complicates about half of the necrotic lesions[2,3]. Patients with extensive necrosis characteristically display clinical evidence of severe sepsis with rapid weight loss. Death usually results from multiorgan failure, days or weeks after the commencement of the attack of acute pancreatitis. Necrosis of the pancreas is present in the majority of patients who die from acute pancreatitis[1,4], hence it is probable that significant improvements in survival from severe acute pancreatitis will be achieved only when appropriate medical treatment is combined with efficient removal of necrotic tissue.

A policy of resectional surgery during the initial days of the attack appears to confer little benefit for survival and may actually increase the risk of mortality, even when confined to patients who remain severely ill despite intensive conservative management[5–7]. Pancreatic resection is a formidable undertaking in an ill patient, and the surgeon is a poor judge of what should be removed and what remains viable[7,8]. Bleeding may be severe both during and after the operation[9] and reoperation is commonly required to remove further accumulated necrotic tissue or to resect ischaemic bowel[10,11]. Patients with acute pancreatitis are highly 'catabolic'[12,13] and death from sepsis is a common sequel to resection[9,10].

An alternative to resection is debridement of the necrotic tissue, often termed necrosectomy or sequestrectomy[14], a procedure described by Moynihan in 1925[15]. A prerequisite to the removal of necrotic tissue is its accurate identification and localization. This has been facilitated by the introduction of computed tomography (CT) combined with intravenous contrast enhancement[16,17]. The operation itself is made easier and the postoperative course smoother if there is a clear plane of demarcation between necrotic and viable tissue, and if granulation tissue has formed, at least partly, in the walls of the cavity containing the necrotic tissue. Thus a 'maturation interval' between the onset of acute pancreatitis and debridement is desirable, but may not be feasible owing to increasing sepsis. Intravenous nutrition enables conservative management to be continued with less danger of progressive nutritional deterioration and without stimulation of enzyme release from the gland.

Recurrent necrosis and sepsis continue to be a problem in many patients after initial removal of necrotic tissue[9,10,18], and traditional methods of drainage, including sump drainage systems, appear to be inadequate to prevent it[19–28]. The fluid that escapes from the drains after pancreatic debridement contains high concentrations of enzymes, which probably ooze from disrupted ductal branches in the wall of the necrotic cavity after debridement. It is probably the continuing release of the enzymes, rapidly activated by necrotic tissue or blood, that causes further digestion and necrosis. The need for secretions

to flow against gravity when the patient is supine, along drains inserted through the anterior abdominal wall, and blockage of the drains by necrotic debris may be contributing factors to the genesis of postoperative sepsis.

Dissatisfaction with existing techniques of drainage has been an incentive to solving the problem of continuing intra-abdominal autodigestion. Repeated debridement or 'open' packing, a reintroduction of the practice first described in 1882 by Rosenbach, has been reported to lower mortality rates to 20–40 per cent[11,29–31], but recovery is usually prolonged, with substantial morbidity. However, it is perhaps the implementation rather than the concept of closed drainage that has been inadequate. Specific properties of a drainage tube for use after pancreatic debridement might include:

1. A diameter large enough to allow egress of necrotic tissue fragments
2. An irrigating channel to dilute and flush away enzyme-rich exudate and to prevent blockage of the drain
3. Sufficient rigidity to prevent distortion and collapse of the drain as it traverses the abdominal wall, but with non-traumatic properties so that erosion of vital structures such as vessels and loops of bowel is minimized
4. Adjustability, so that it can be repositioned easily as the cavity shrinks
5. The drain should be sited so that gravity assists rather than hinders drainage when the patient is supine
6. A closed drainage system is preferable to reduce the risk of infection and of digestion of the skin around the entry site.

In this report, a technique of closed drainage is described in patients who developed pancreatic necrosis after acute pancreatitis.

Patients and methods

Fourteen patients with pancreatic or peripancreatic necrosis underwent debridement and were treated using a dedicated closed drainage system. The age range of patients was from 17 to 77 years (median 54 years), and there were 11 men and three women (*Table 1*). Gallstones were identified in five patients, alcohol abuse in three and a pancreatic neoplasm in one case; one patient developed acute postoperative pancreatitis, and blunt trauma led to acute pancreatitis in one patient. The Ranson scores[32] (median 5) and Imrie scores[33] (median 3) confirm the initial severity of the attacks. Five of the patients were referred from other hospitals.

Each patient developed pancreatic necrosis, which was defined as the presence of one or more areas of necrotic pancreatic and peripancreatic tissue greater than 5 cm in diameter. Patients in whom collections of fluid or pus were the dominant element (*Figure 1a*), rather than solid necrotic tissue (*Figure 1b*), were not included as they were generally treated by internal drainage methods or guided percutaneous aspiration. Intravenous nutrition without oral food intake was instituted within 10 days of admission when it became clear that an early return to normal diet was not possible or that a pancreatic collection was probable.

Although pancreatic necrosis was suspected clinically, CT was most accurate, confirming the diagnosis and localizing the necrotic tissue, in 11 patients (*Table 1*). Three patients were treated before CT was routinely available at the General Infirmary. The diagnosis was confirmed at laparotomy in two patients, and in one case ultrasound scanning demonstrated a pancreatic collection within which solid necrotic tissue was visualized.

Before April 1986, CT was performed in seven patients using a Tomoscan 300, 310 or 350 scanner (Philips Medical Systems Ltd., London, UK). Upper abdominal scans were obtained after oral or nasogastric administration of 500 ml of a 3 per cent solution of Gastrografin® (10 per cent sodium diatrizoate, 66 per cent meglumine diatrizoate; Schering Pharmaceuticals, Burgess Hill, UK). Images of 12-mm thickness were obtained through the upper abdomen, and the pancreas was targeted. A rapid sequence of 6-mm thickness scans through the pancreas was carried out, at 15-s intervals, immediately after intravenous injection of concentrated contrast medium (50–100 ml of either 65 per cent meglumine diatrizoate (Urografin 310M®, Schering Pharmaceuticals) or 65 per cent iohexol (Omnipaque 300®, Nycomed (UK) Ltd., Birmingham, UK). In the four most recent cases, intravenous contrast CT angiography was performed[16,17] using a CT9800 scanner with a dynamic imaging facility (IGE Medical Systems Ltd., Slough, UK). Oral contrast medium was administered as before and 10-mm thickness scans were obtained. Non-ionic contrast medium (76 per cent iopamidol, Niopam 370®, E. Merck Ltd., Alton, UK) in a dose of 1·5–2 ml/kg body-weight (0·55–0·75 g iodine/kg) was injected as a rapid intravenous bolus, and a series of 10–12 incremental scans of 5-mm thickness were obtained dynamically through the entire pancreatic area (scan time 2 s, cycle time 8 s; *Figure 2*). Contrast enhancement values below 30 Hounsfield units were considered indicative of pancreatic necrosis[16].

The aim of management was to wait for at least 1 month, if possible, before proceeding to debridement, to enable the necrotic tissue to separate and the cavity to develop a well-defined wall. In five cases an operation was performed at an earlier stage when it became clear that sepsis was becoming life threatening despite intravenous nutrition and antibiotics (*Table 1*). In nine cases, it was possible to delay operation by more than 4 weeks, but evidence of continuing sepsis was present at the time of operation; in five of these patients sepsis was sufficiently severe for the operation to be carried out urgently, while in two of them emergency laparotomy was performed because a complication developed. In the 48 h before operation the range of peak leucocyte count was 8·2–47·1 × 10^9/litre (median 17·5) and the peak temperature range was 37·4–40·4°C (median 39·4°C). Preoperative Medical Research Council (MRC) sepsis scores[34] were in the range 9–31 (median 16) while APACHE-II scores[35] ranged from 7 to 38 (median 17, *Table 1*).

A midline incision was made in the first three patients and in two other patients who had a midline scar from a previous laparotomy. In nine cases, a bilateral subcostal incision ('rooftop' or 'chevron' incision) was employed. In nine patients, access to the necrotic cavity was gained by lifting up the transverse colon and applying digital pressure through the weakened and oedematous tissues at the root of the mesocolon in the vicinity of the duodenojejunal flexure. It was then possible to explore the cavity and its ramifications digitally, removing the necrotic tissue. Samples of necrotic tissue were sent for histological examination, immediate Gram staining, and aerobic and anaerobic culture. In one patient, who underwent operation on the tenth day of the attack (case 13), the necrotic pancreas was insufficiently friable for digital debridement, and sharp dissection was needed to transect it.

A specially designed drain made from silicone elastomer tubing with an outside diameter of 20 mm is shown in *Figure 3*. In the original hand-made version, a cuff of thin silicone elastomer sheet was bonded to the internal end (*Figure 3*) to prevent trauma to vessels and neighbouring viscera. An irrigating tube inside the main channel is brought out through the side wall, making this a closed system, and this tube accepts a standard male Luer connector. The drainage tubes are now manufactured with the cuff incorporated into the moulding (*Figure 3*) (Fehling Medizintechnik GmbH, Karlstein, FRG) and can be obtained from Medical Bionics, PO Box 63, Wokingham, UK. The drains were inserted into the cavity, from which the necrotic tissue had been removed, by two principal routes. By pushing a finger through the weakest point in the tail of the pancreas, a drain could be drawn into the central cavity using a long pair of artery forceps passed through

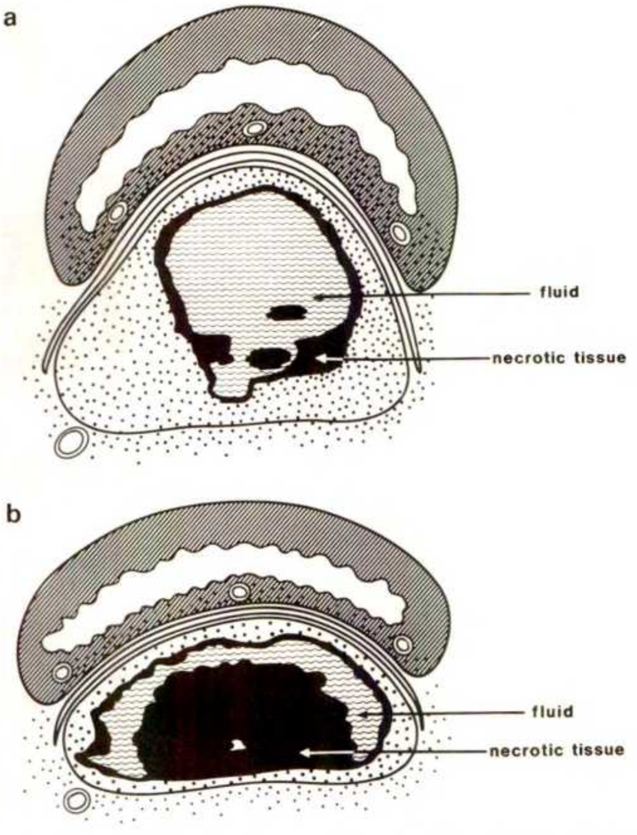

Figure 1 *Diagrams of* **a** *pancreatic abscess, an encapsulated collection of frank pus containing bacterial organisms, but only a relatively small amount of necrotic tissue, and* **b** *pancreatic necrosis in which necrotic tissue is the dominant element and may be surrounded by small amounts of pus. the access point in the transverse mesocolon (*Figure 4a*). Similarly, if there was cavitation in the head of the pancreas, a drain was introduced retroduodenally after Kocherization (*Figure 4b*). In five patients, drains were placed through the head and tail of the gland, and in nine patients a single drain was used (three via head, six via tail). In three patients, a small subsidiary silicone elastomer tube drain (7-mm diameter, Easyview®, Dow Corning Ltd., Reading, UK) was inserted through the access point in the transverse mesocolon. After insertion of the drains, the mesocolic access point was closed with silk sutures in order to isolate the cavity from the greater sac, and in two instances packs of non-adherent, soft paraffin-impregnated gauze (Jelonet®, Smith and Nephew Ltd., Hull, UK) were inserted in the proximity of the debrided area to ensure haemostasis. These were removed at re-laparotomy the next day. The drains were brought out through the abdominal wall as posteriorly as possible in order to ensure dependent drainage (*Figure 4c*). If the cavity was large and the drains extended for some distance within it, small side holes were fashioned. Flanges made from silicone elastomer were used to anchor the drain to the skin (*Figure 3*). The drain was pulled through the central hole in the flange, which was attached to the skin using three or four silk sutures. The drain was a sufficiently tight fit within the flange that dislodgement did not occur.

The debrided cavity was irrigated with 2 litres of saline per day, administered as an hourly bolus in order to 'flush' the cavity. When the return fluid was clear, usually after 7–10 days, the volume was reduced to 1 litre daily. Recently we have added an antiprotease, Trasylol® (Bayer UK Ltd., Newbury, Berks, UK), at a concentration of 1×10^6 kallidinogenase inactivator (KI) units in each litre of saline (seven patients). A sinogram was carried out weekly by injecting radio-opaque contrast medium (25–40 per cent sodium diatrizoate, Hypaque 25® and Hypaque 40®, Sterling Research Laboratories, Guildford, UK) via the irrigation channel. This enabled the position of the drain to be adjusted so that there was free drainage of the cavity. Drains were removed when the cavity closed.

Results

The extent of necrosis, results of bacteriological investigations, and other data are shown for each patient in *Table 2*. Extensions of the necrotic cavity beyond the confines of the pancreas were present in five cases. The wet weight of specimens varied from 30 to 160 g (median 90 g). The median period of irrigation after operation was 19 days. The median amylase concentration from the irrigated drains of six patients during the first week after debridement was 48 000 units/litre. We did not determine protease concentrations independently but would expect levels to be similarly elevated. In addition, the drainage fluid was characteristically 'prune juice' coloured, suggesting continuing digestion. Under these circumstances, inclusion of an antiprotease seemed logical. After Trasylol was added to the irrigating fluid, the dark colour of the drainage fluid disappeared within 48 h.

Bleeding into the drain occurred in one case, but this resolved spontaneously. Infection complicated all of the midline wounds but none of the transverse incisions. Fistulae between the cavity and bowel were revealed at sinography in six patients. In four cases the cavity communicated with jejunum, and in two cases with both jejunum and colon. In two cases, a communication with the pancreatic duct was observed. However, there was no clinical evidence of fistula formation and specific treatment was not required; all fistulae closed spontaneously. The drains were removed, under radiographic control, between 13 and 41 days after debridement (median 30 days in survivors). Intravenous nutrition was discontinued when the patient was able to return to a normal diet and major discharge from the drain site had ceased. The median duration of intravenous nutrition was 37 days (range 11–98 days). Patients were discharged from hospital 26–140 days after operation (median 44 days). No patient developed colonic ischaemia.

Three patients died. One was a woman of 77 years, with overwhelming sepsis at the time of operation and established respiratory, cardiovascular and renal failure. Debridement, which was performed 21 days after admission, did not appear to influence the course of her illness. She died 6 days postoperatively and autopsy revealed gross pulmonary oedema. A 71-year-old man died 50 days after operation from the complications of a small bowel fistula not directly related to the pancreas but caused while gaining access to the abdomen. He had suffered a shrapnel injury during World War II and there were dense adhesions throughout the abdomen. A man of 68 years, with severe chronic respiratory disease, angina and hypertension, who had established renal failure at the time of admission to hospital, developed intractable multiorgan failure and coagulopathy. By computed tomographic angiography with guided needle aspiration, it was shown that he had infected peripancreatic necrosis. Debridement was carried out on the 15th day of the attack, but did not influence the multiorgan failure, and he died 4 days later.

The 11 survivors were followed for periods from 8 months to 7 years. Three were diabetic; in two cases only dietary

Table 2. *Postoperative details of patients*

Case	Location of pancreatic necrosis	Extrapancreatic extension	Bacterial organisms cultured	Sites of insertion of drainage tubes	Irrigation period (days)†	Drainage period (days)†	Outcome

treatment was required, while one patient required insulin therapy. None of the patients complained of steatorrhoea. All remain well, with the exception of one patient who subsequently died from a disseminated carcinoma of the head of the pancreas, probably the cause of his attack of acute pancreatitis but which was unrecognized at the time of debridement.

Discussion

In this report we have used the terms pancreatic necrosis and peripancreatic necrosis to mean an extensive area of the pancreas or peripancreatic tissue which was necrotic although, inevitably, pus, fibrin and blood were also present. In each case necrosis occurred as a consequence of acute pancreatitis and resulted in a severe, 'septic' illness characterized by pyrexia and leucocytosis, although organisms were cultured from only 11 samples of necrotic tissue (79 per cent), and blood cultures were negative. The term pancreatic abscess has also been used to describe similar lesions in the pancreas, but we feel it is more appropriate to use it if pus is the major component rather than necrotic tissue. The weight of necrotic tissue removed ranged from 30 to 160 g, and tissue was principally peripancreatic in one patient.

The management of pancreatic necrosis has become more precise with the development of CT, particularly with the use of intravenous contrast enhancement[16,17,30]. Ultrasound is of little value for the identification of necrotic tissue[17,36]; the clinical evaluation of the patient is unreliable, and the surgeon's ability to distinguish viable from necrotic tissue has been found wanting[7,8,37]. The use of high-dose intravenous contrast enhancement (0·55–0·75 g iodine/kg body-weight) and dynamic scanning improves the precision of CT[17,30] and enables a more accurate delineation of pancreatic from peripancreatic necrosis. Notwithstanding their value, CT appearances alone are inadequate as an indication of the need to intervene surgically, and other patients we have treated have shown gradual improvement and eventual resolution of sepsis, despite equivocally abnormal CT contrast enhancement. Thus our policy has been to continue conservative management until the need for operation becomes imperative on clinical grounds, using CT to monitor the progress of changes in the pancreas. When operation was undertaken, however, CT provided a most valuable guide to the location and extent of necrotic tissue. The timing of operative intervention is probably important. Operations carried out during the initial days of the attack are frequently fatal[5,9], and delay to permit diagnostic investigations and to allow clear demarcation of the necrotic tissue appear warranted. Nevetheless, it is important to operate before multiorgan failure has become established, or the mortality rate is also likely to be high[10,38]. The patient who becomes severely ill with a necrotic pancreas during the initial days of the attack places the surgeon on the horns of a dilemma. Certainly, a trial of continued conservative management incorporating intravenous nutrition, even in the presence of very severe sepsis, appears justified because in our experience complete resolution may occur. At laparotomy, oedema of the peripancreatic tissues and thickening of the omentum and mesocolon make assessment of the pancreas difficult.

Access to the necrotic area through the root of the transverse mesocolon, also recently advocated by others[37,39], was found to be simple and convenient in nine of the patients. While such access does not permit the thorough examination of the pancreas and posterior abdominal wall that can be obtained by extensive division of the gastrocolic omentum, it entails considerably less trauma and blood loss. Moreover, the more traditional gastrocolic approach breaks down the 'capsule' that forms around the necrotic material, and thus allows pancreatic juice to disseminate widely in the upper abdomen postoperatively and to contribute to continuing necrosis. The approach via the transverse mesocolon can be closed easily after the insertion of drainage tubes and thus permits closed cavity irrigation to be carried out.

The need for irrigation is controversial. It has been strongly recommended by some authors[38,40–42] but others have used multiple, soft, tubular drains without irrigation[39] and have achieved apparently comparable results. We have used irrigation as a logical method of scavenging the cavity, and to prevent the accumulation of erosive pancreatic juice. In the first postoperative week, the effluent from the drainage tube has the appearance of the 'prune juice' fluid that accumulates within the peritoneal cavity during severe acute pancreatitis. Combined with high levels of pancreatic enzymes, the appearance suggests that enzymes are activated locally (by necrotic tissue, leucocyte enzymes or blood) with resultant autodigestion. For this reason we added aprotinin (Trasylol) to the irrigation fluid for the seven most recent patients, and it appeared that the colour of the fluid resolved more rapidly. A closed system was employed to prevent ingress of infection, and appears to have achieved its aim.

There was a high incidence of bowel fistulae, as visualized on the postoperative sinograms. Nevertheless clinical problems were not identified with fistulae and there was no drainage of intestinal fluid via the drains. All would have gone unnoticed if frequent sinograms had not been obtained. We believe that regular sinograms were justified, because in four patients it was found that the cavity had contracted so that drainage became inefficient.

The use of gauze packs[29–31] and frequent relaparotomy[11], which has become fashionable recently, is an alternative method to remove the erosive juice that exudes from the cavity after debridement, the pack acting as a sponge. We favour the concept of closed cavity irrigation, but careful design and placement of the drainage tubes is probably crucial to success. The features that have been incorporated into the system described (wide bore, atraumatic, resistant to collapse, irrigating facility, adjustability and gravity-assisted drainage) make it as different from traditional drainage tubes as open packing. Recent studies of carefully carried out drainage appear to be as successful as open packing techniques from the standpoint of mortality[39,41], and reoperation was not a frequent requirement.

In the present study, three of 14 patients died (21 per cent), but all were aged over 65 years and the youngest of them was already chronically ill with established multiorgan failure at the time of admission with acute pancreatitis. Survival from pancreatic necrosis is less common in patients aged 60 years or more[43] and, in our opinion, it is unlikely that the open packing technique would have secured survival in the patients who died. A randomized study may be necessary to decide the issue—a daunting prospect.

Open abdomen technique in the treatment of peritonitis

V. I. Korepanov

Block 2, Apartment 13, 115446 Moscow, USSR

To stimulate the interest of Russian surgeons in the open technique for the treatment of peritonitis, I recently reviewed the reports of foreign investigators[1,2]. All such authors refer to Steinberg[3,4], who has been acknowledged as a pioneer of the method. I do not wish to detract in the slightest from the outstanding role of Steinberg in developing this new technique, however, it should be noted that the method had grown from the Mikulicz technique elaborated at the end of the last century. This method was modified slightly by the French surgeon Faure[5] who used it to treat pelvic abscesses and peritonitis in women. Faure prepared a sac from multilayered gauze and placed it deep into the pelvis; long narrow gauze tampons were put into the sac to fill the pelvic cavity. The author left the abdominal cavity open for 9–10 days, but beginning on the third day he removed from two to four tampons a day, completing withdrawal by the ninth or tenth day. The final stage consisted of closure of the abdomen. A similar technique of abdominal tamponage was used by Anderson *et al.*[6] who packed the lateral spaces of the abdominal cavity, covering the viscera with a gauze pack. Unfortunately, the results were discouraging, the mortality rate reaching 60 per cent.

Steinberg[3] proposed a more gentle approach leaving the abdominal cavity open with the viscera covered by a large gauze pack for not more than 72 h. As a result only one patient died of the 14 (7 per cent) so treated. For severe peritonitis he recommended that the pack should be kept in position for up to 10 days because more frequent changes could cause intestinal fistula formation[4]. Using this technique 17 per cent of patients died.

In 1984 the Russian surgeon Makhocha[7] reviewed his personal experience with the open abdomen technique in 128 patients suffering from severe peritonitis, 106 of whom survived (83 per cent). He referred to his first communication dated 1967 and based on his originally elaborated technique which had been applied as early as 1949[8]. This report was published in Russian in the *Proceedings of the Ukraine Scientific Surgery Society* in Kiev and remained unknown not only to foreign surgeons but also to Russian surgical circles. A translation of that article is as follows:

> The source of peritonitis is eliminated and the abdominal cavity dried but not lavaged. A large (40 × 40 cm) two-layer gauze napkin is sutured in the centre by a strong silk ligature. This napkin covers the viscera, its borders overlapping the wound edges by 5–6 cm. The ligature is pulled up and the space in the centre of the napkin is filled with from four to eight gauze tampons, the ends of which are located outside the wound. Alongside the tampons catheters are put into the abdominal cavity for instillation of antibiotics. Two all-layer sutures are placed through both the upper and lower angles of the midline abdominal wound. The integral parts of a dressing are fixed in position with the help of a large long towel wrapped tightly around the patient's body. In the postoperative period the superficial layers of the dressing are changed as soon as they become wet. Tampons are gradually withdrawn starting from the fourth day; this procedure is completed by the 10th to 15th day. Then the napkin is pulled out, using the silk ligature, step by step and removed by the 18th to 21st day.

In the initial study of 26 patients all but four survived (85 per cent), excellent results when taking into consideration the fact that five patients required an enterostomy. In his last article[7] the author advised changing the tampons every 2–3 days, leaving the napkin longer until body temperature and intestinal motility returned to normal.

Presently, we have available at least three articles by Russian surgeons published in the domestic medical literature[9–11] that deal with the open abdomen technique for advanced peritonitis with a 17 per cent mortality rate. This short report may alert foreign specialists in abdominal surgery to investigations conducted by Russian surgeons.

Threshold for albumin as a prognostic marker in acute pancreatitis

M. P. Holliday, D. Shaw, W. M. Thomas* and T. Leese*

*Department of Chemical Pathology and *Department of Surgery, University of Leicester, Leicester, UK*

Correspondence to: Dr M. P. Holliday, Department of Chemical Pathology, Leicester Royal Infirmary, PO Box 65, Leicester LE2 7LX, UK

Several multifactor prognostic scoring systems for acute pancreatitis use serum albumin[1–3]. The prognostic threshold of 32 g/l derives from an assay using bromocresol green dye-binding reagent, calibrated against purified human serum albumin[4]. This method routinely over-estimates serum albumin when calibrated against a purified human serum albumin standard, which is common practice[5]. This positive error has a magnitude of 2–12 g/l and arises from interference by α- and β-globulins, which include some of the acute phase proteins[5–7]. Bromocresol purple reagent is specific for albumin[5,7]. More than 10 per cent of UK laboratories now use bromocresol purple routinely, as does the Abbott Vision analyser (Abbott Laboratories, Chicago, USA), an instrument conveniently used for albumin measurement on emergency samples[8].

The magnitude of the globulin error in acute pancreatitis has not previously been evaluated. This study was designed to determine the corresponding bromocresol purple–albumin threshold in an established bromocresol purple assay in routine use and in the Abbott Vision bromocresol purple method.

Patients and methods

Sixty-four patients (32 men) were recruited randomly from hospital admissions for acute pancreatitis in Leicestershire over 23 months. Serum was collected within 24 h of admission. The mean age was 58·3 years (range 17–87 years). Twenty-six cases were scored as prognostically severe on admission according to the Glasgow criteria[1]. Aetiologies and complications are shown in *Tables 1* and *2*. The albumin assays are outlined in the Appendix to this paper.

Results

Scatterplots of results from the established bromocresol purple and Abbott Vision bromocresol purple methods *versus* the bromocresol green method are shown in *Figures 1* and *2*. Regression parameters are summarized in *Table 3*. The regression equations by Deming's method (with 95 per cent confidence intervals for the slope) are:

Established bromocresol purple–albumin (g/l) = −5·11 + 1·02 (0·96 – 1·08) bromocresol green–albumin (g/l)

Abbott Vision bromocresol purple–albumin (g/l) = −4·88 + 1·04 (0·99 – 1·09) bromocresol green–albumin (g/l)

The standard *y*-on-*x* regression equations are:

Established bromocresol purple–albumin (g/l) = 0·50 + 0·87 bromocresol green–albumin (g/l)

Abbott Vision bromocresol purple–albumin (g/l) = −2·72 + 0·98 bromocresol green–albumin (g/l)

Bromocresol purple–albumin thresholds (with 95 per cent confidence intervals) predicted from the standard regression lines where bromocresol green–albumin = 32 g/l are:

Established bromocresol purple method 28·3 (27·6 – 29·1) g/l

Abbott Vision bromocresol purple method 28·7 (28·0 – 29·4) g/l

Table 1 *Aetiologies of acute pancreatitis in the 64 patients studied*

No complications	49	77

* Pseudocyst, pancreatic abscess, ileus, gastrointestinal haemorrhage, pleural effusion, pneumonia, congestive cardiac failure

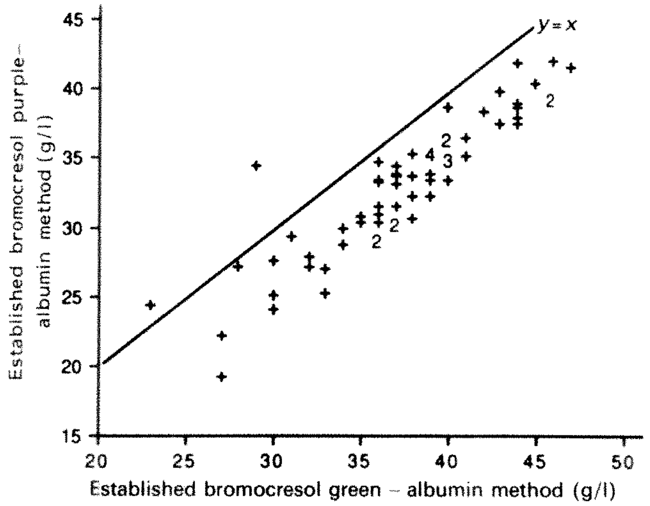

Figure 1 *Scatterplot of an established bromocresol purple–albumin method against an established bromocresol green–albumin method in acute pancreatitis sera*

Discussion

The Deming slopes do not differ significantly from unity at the 5 per cent level of probability. This is consistent with the presence of a constant bias in bromocresol purple–albumin results with respect to bromocresol green–albumin over the range studied. The magnitude of the bias, about −5 g/l, is similar to that reported in sera from other sources[7].

The accuracy of the bromocresol green assay used here approximates closely to the UK national average performance for this method as measured by the UK External Quality Assessment Scheme for General Clinical Chemistry (UKEQAS for General Clinical Chemistry, Wolfson Research Laboratories, Birmingham, UK). During the study bromocresol

0007–1323/89/050472–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

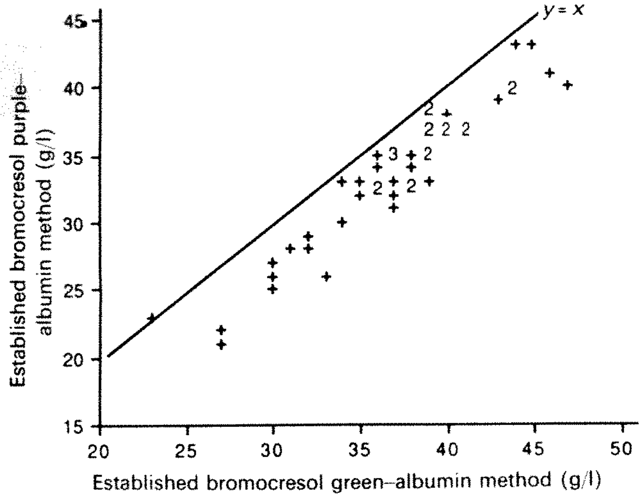

Figure 2 *Scatterplot of the Abbott Vision bromocresol purple–albumin method against an established bromocresol green–albumin method in acute pancreatitis sera*

green–albumin results from this laboratory carried an average bias of +0·8 per cent with respect to the national mean for continuous flow methods using succinate buffer ($n = 91$). Results were on average 2·0 per cent from this target value, which compares with a national interlaboratory coefficient of variation of about 4·0 per cent for this method.

Predicted bromocresol purple thresholds were 28·3 g/l from the established assay and 28·7 g/l from the Abbott Vision assay. It is recommended that where bromocresol purple is used the prognostic threshold be adjusted to 28 g/l, or to 28·5 g/l if results are reported to three significant figures or obtained from the Abbott Vision analyser.

The bromocresol purple method for albumin is gaining popularity and users of prognostic scoring systems in acute pancreatitis should be aware of the chemistry of their local method.

Acknowledgements

The authors would like to thank Dr P. G. Hill of Derbyshire Royal Infirmary and Mr A. Fenton of Leicester Royal Infirmary for assistance with the established albumin assays, and Mrs Rosalind Aldwinckle for typing the manuscript.

Appendix I

Albumin assays

1. An established bromocresol green method[9] on a Technicon SMAC II (Technicon Instruments Corporation, New York, USA) continuous flow multichannel analyser (pH 4·2 succinate buffer, 60 s reaction time), using Technicon SMAC calibrators, themselves calibrated against a gravimetric Cohn fraction 5 human serum albumin standard using the same reagent[10]. The standard deviation of within-run analytical imprecision at 29 g/l was 0·51 g/l.

2. An established bromocresol purple method[11] on a discrete multichannel analyser (pH 5·5 0·1 M acetate buffer, 0·09 mmol/l bromocresol purple, ionic strength adjusted with sodium chloride to a final chloride concentration of 0·15 mol/l), using pooled human serum as calibration material, itself calibrated immunochemically against the Sheffield (UK) Protein Reference Unit standard SPS-01 (PRU Central Antiserum Purchasing Unit, Royal Hallamshire Hospital, Sheffield, UK). The standard deviation of within-run analytical imprecision at 25 g/l was 0·20 g/l.

3. The Abbott Vision bromocresol purple method (pH 5·4 0·125 mol/l acetate buffer, 0·19 mmol/l bromocresol purple), using calibrators supplied by the manufacturer. The standard deviation of within-run analytical imprecision at 36 g/l was 0·47 g/l.

Data analysis

The standard least-squares regression line of bromocresol purple–albumin results on bromocresol green–albumin was used to predict the corresponding bromocresol purple–albumin thresholds. Deming's least-squares regression formula, which takes account of analytical imprecision in the independent variable, was used to obtain estimates of the slope appropriate for the detection of proportional (concentration-dependent) bias[12,13]. Within each assay the standard deviation of analytical imprecision was assumed to be constant over the range of concentrations encountered.

Mesoatrial shunt: a surgical option in the management of the Budd–Chiari syndrome

The Budd–Chiari syndrome, arising from hepatic venous outflow obstruction, is frequently complicated by inferior vena caval occlusion or obstruction. Satisfactory decompression of the liver by either portacaval or mesocaval shunts may therefore prove impossible or be prone to failure from shunt thrombosis. The mesoatrial shunt which allows the portal vein to drain directly into the right atrium has previously been advocated in this situation. Five patients with the Budd–Chiari syndrome and caval occlusion and/or obstruction have had mesoatrial shunts constructed using externally supported polytetrafluoroethylene grafts. A single thoracoabdominal incision, incorporating a median sternotomy, was found to provide a satisfactory approach. All patients recovered well with resolution of ascites, diminution in liver size and improvement in inferior vena caval pressure gradients. Furthermore, all shunts have remained patent, as determined by Dopper flow studies and contrast-enhanced computed tomographic scanning, during follow-up periods ranging from 9 to 16 months. If these results are supported by longer term studies, the mesoatrial shunt may become the surgical treatment of choice in patients with hepatic vein occlusion and the Budd–Chiari syndrome associated with inferior vena caval obstruction.

Keywords: Budd–Chiari syndrome, portosystemic shunts, portal hypertension, vena cava, obstruction

Hepatic venous outflow obstruction was originally reported by Budd in 1845[1] but the first description of the clinical syndrome of hepatomegaly, ascites and abdominal pain is attributed to Chiari in 1899[2]. The clinical features may follow inferior vena caval obstruction or hepatic vein thrombosis and/or obstruction. The syndrome also develops with central hepatic veno-occlusive disease[3]. These processes may reflect an underlying predisposition to venous thrombosis such as that, which occurs in overt or latent myeloproliferative disorders[4], paroxysmal nocturnal haemoglobinuria, pregnancy and in women using the oral contraceptive pill. Less common causes include inferior vena caval webs (particularly in Japan[5]), trauma and tumours (principally renal, adrenal and hepatocellular carcinomas).

The disease runs a variable clinical course ranging from an acute, rapidly fatal illness[6,7] to a more usual chronic condition characterized by progressive ascites and wasting and accompanied by cirrhosis and portal hypertension. Despite the very rare cases of spontaneous resolution[8], most patients have a poor prognosis with only 50 per cent surviving for 2 years[9]. With the increasing recognition of the limitations of medical therapy there has been a proliferation of reports describing surgical solutions to the syndrome. These have largely dealt with portosystemic shunting. In preparing patients for such operations, imaging studies of the inferior vena cava (IVC) have revealed a high incidence of obstruction or occlusion of the IVC[10–14], which seriously prejudices the patency of these shunts and thus their effectiveness in decompressing the congested liver. To avoid these difficulties, Cameron and Maddrey[15] described the mesoatrial shunt which allows the portal venous system to drain directly into the right atrium, bypassing the inferior venal caval obstruction.

We have constructed a mesoatrial shunt, with some technical operative modifications, in five patients with the Budd–Chiari syndrome and report our early results of clinical outcome and shunt patency.

Patients and methods

The patients in this series (four female, one male) ranged in age from 14 to 54 years and all presented with hepatomegaly, massive ascites and various degrees of malnutrition. A diagnosis of Budd–Chiari syndrome was confirmed by hepatic venography in all cases and by preoperative liver biopsy in three patients. The condition was associated with an underlying myeloproliferative disorder in four of the five cases. Investigations also included ultrasound and computed tomographic (CT) scanning, inferior vena cavography with pressure measurements from the right atrium and the infrahepatic cava (*Figure 1*), and mesenteric arterioportography which provided an assessment of the size and patency of vessels in the portal venous system[16,17]. Superior mesenteric vein diameters estimated radiologically were 12–13 mm. All five patients had evidence of obstruction or occlusion of the IVC (*Table 1*). The indications for surgery included: medically intractable ascites, deteriorating liver function with Rappaport zone 3 necrosis in the liver biopsy specimen, and progressive cachexia and wasting.

Patients were prepared for surgery by regular paracentesis (and thoracocentesis in one case), vitamin K, diuretics (spironolactone and frusemide) and 48 h of oral therapy with metronidazole, neomycin and lactulose. No specific haematological measures were undertaken, other than to discontinue anticoagulants in the two patients who were receiving these for myeloproliferative disorders.

After anaesthetic induction, monitoring catheters were inserted to record the following: arterial pressure and blood gases; pulmonary artery pressure, pulmonary capillary occlusion pressure and cardiac output; central venous pressure and urine output. Cardiac output was determined in all patients by a thermodilution technique utilizing a flow-directed pulmonary artery catheter. Measurements were made throughout the operative period and immediately before and after shunt opening. In two patients, cardiac output was measured continuously by Doppler or impedance techniques.

Operative details

After an initial laparotomy via a midline abdominal incision, the superior mesenteric vein was dissected free in the root of the small bowel mesentery. After proximodistal control, a 2–3-cm length of the vessel was isolated for the anastomosis. A median sternotomy was carried out in a synchronous combined manner and the pericardium

0007–1323/89/050474–05$3.00 © 1989 Butterworth & Co (Publishers) Ltd

was opened. The lateral wall of the right atrium was cross-clamped just below the auricle and 5000 units unfractionated heparin was given intravenously. A 13-mm spirally reinforced expanded polytetrafluoroethylene (PTFE) graft (Impraflex® Impra Incorporated, Arizona, USA) was sutured obliquely end-to-side to the superior mesenteric vein and to the right atrium with continuous 5/0 Prolene® (Ethicon Ltd., Edinburgh, UK). The graft follows an S shaped route from the atrium, through a subxiphoid V shaped incision in the diaphragm, around the left lobe of the liver passing anteriorly to the stomach and through the transverse mesocolon (*Figure 2*). Portal vein pressures were recorded before and after construction of the shunt. After haemostasis, the wounds were closed (but not the pericardium) with a pericardial drain and an abdominal wound drain.

The patient was electively ventilated for at least 24 h with close monitoring of cardiovascular, pulmonary, renal and haematological functions. Drains were removed within 72 h. Prophylactic antibiotics were continued until invasive monitoring lines were withdrawn and prophylactic H_2 antagonists and parenteral nutrition were continued until enteral feeding was re-established. Patients were commenced on subcutaneous low-dose heparin prophylaxis (5000 units twice daily) if and when the prothrombin time became less than twice normal.

Results

A satisfactory mesoatrial blood flow was established through the graft in each case with concomitant reduction in the portal venous pressure (*Table 1*). Creation of the shunt resulted in a dramatic rise in cardiac output in two patients (Nos. 2 and 3) from 4·5 to 6·8 litres/min and from 5·0 to 7·0 litres/min, respectively. A less marked increase in cardiac output (from 4·9 to 5·0 litres/min (No. 1), from 3·4 to 4·0 litres/min (No. 4) and from 3·9 to 4·0 litres/min (No. 5)) was observed in the other three patients. These results obtained by thermodilution were mirrored by the continuous measurements using Doppler impedance methods. We experienced no operative mortality although the postoperative course in patient No. 1 was complicated by hypotension and oliguria requiring inotropic support and basal pneumonia exacerbated by severe respiratory weakness secondary to malnutrition. Another patient (No. 3) developed postoperative bleeding from the pericardial drain (maximum 500 ml/h) which ceased after correcting his coagulopathy.

All patients subsequently made good recoveries with resolution of ascites and striking improvements in nutritional status and general well-being. Furthermore, all shunts have been demonstrated to be patent by means of Doppler ultrasound studies (reversed flow in the portal vein and turbulent flow in the shunt) and dynamic CT scanning (*Figure 3a* and *b*). CT scans have also revealed significant reductions in liver size with diminution of the caudate lobe in all patients. Doppler studies have indicated increased hepatic

Discussion

Controversial surgical aspects of the Budd–Chiari syndrome relate firstly to the indications for surgery, secondly to the optimal surgical approach, and thirdly to details of operative technique. The relative rarity of this condition in the West and the consequent absence of controlled clinical trials do not enable any definitive statements on these problems but some conclusions can be drawn from the surgical literature.

It seems likely that surgical treatment is superior to conservative therapy alone[3,6,14] since the majority of patients managed conservatively die within 2–3 years of presentation[9,18], although medical therapy can occasionally be compatible with long-term survival[19]. Few would dispute that medically intractable ascites, rapidly deteriorating liver function and progressive wasting merit surgical intervention. Added to this, Millikan *et al.*[8] have suggested that the presence of severe zone 3 necrosis on a liver biopsy specimen signifies a failing liver and the need for surgical treatment. These indications continue to broaden as the operative mortality of shunt surgery diminishes and postoperative survival increases[20,21]. Furthermore, the improved quality of life with freedom from ascites and the apparent absence of late encephalopathy has prompted several authors to recommend urgent portosystemic shunting in all patients with symptomatic Budd–Chiari syndrome[12,20,21].

The lack of any consensus about the best surgical approach is reflected by the wide variety of operations designed to relieve this condition (*Table 2*). This is related partly to the differing anatomical aetiologies of the Budd–Chiari syndrome; in Japan and China, membranous and segmental obstruction of the IVC are relatively common causes of the syndrome[5,7] and direct operations are more often performed. In contrast, in the West, hepatic vein occlusion is the more usual primary pathology and shunting procedures have tended to be performed. Portosystemic shunting is effective since it converts the portal vein into an outflow tract, thus decompressing the massive hepatic congestion and reducing hepatic sinusoidal pressure towards normal[22]. Side-to-side portacaval shunting is regarded as the method of choice by many[7,8,21,22] but occlusion or obstruction of the IVC, due to thrombosis or caudate lobe compression respectively, either precludes or militates against a successful outcome[3,12,14]. Caudate lobe hypertrophy, which develops because its veins drain directly into the cava independently of the main hepatic veins, frequently makes side-to-side portacaval shunting impossible[23]. Because of these difficulties, mesocaval interposition shunting has been recommended. However, the excellent results reported by Vons *et al.*[20], even with mesocaval pressure gradients as low as 5 mmHg, have not been repeated by others in patients with the Budd–Chiari syndrome[11,14] or in other cases of portal hypertension[51,52]. This may be partly related to the use of autologous vein rather than prosthetic material for the interposition shunt. Even accepting this, however, the patent mesocaval shunt may still fail to control symptoms in the presence of obstruction of the IVC[14,28].

The mesoatrial shunt was first successfully reported by Cameron and Maddrey in 1978[15] although a similar graft connected to an internal iliac artery fistula had been previously described[53]. The objective of the shunt is to provide portosystemic decompression in the presence of an occluded IVC, and the indications have since been extended to include patients with caval obstruction. The haemodynamics of this shunt have recently been reported[54] and our patients demonstrated similar acute changes in cardiac output and portal vein pressure upon opening the shunt. The route for the graft that we adopted involved a median sternotomy rather than a right lateral thoracotomy and we believe this to be a significant advantage since it eliminates the risk of a prolonged pleural leak of ascites[14,25,34]. Some surgeons have criticized this long prosthetic shunt as being prone to thrombosis[8,34,36]. This is partially borne out by reports in the literature (*Table 3*) but these results are likely to improve with the use of externally supported expanded PTFE grafts. This material is easy to handle, is alleged to have a thromboresistant potential, develops

only a thin neointima, and has been used successfully for shunts in portal hypertension and in the Budd–Chiari syndrome[34,57,58]. Moreover, the external spiral reinforcement should eliminate graft compression in the subxiphoid tunnel, which can be a problem[59]. The Impraflex mesoatrial shunt with its high blood flow encouraged by the abdominothoracic pressure gradient, its wide diameter, moderate rigidity and low thrombogenicity fulfils most of the criteria for a successful venous bypass graft[60]. Additionally, the use of maintenance low-dose heparin prophylaxis in these patients may be of further benefit.

However, if doubts about the long-term patency of the mesoatrial shunt are subsequently confirmed, then a two-stage approach to the Budd–Chiari syndrome associated with obstruction of the IVC may be the solution. This would entail an initial mesoatrial shunt which would be replaced by an elective portacaval shunt a few months later when the liver had decompressed and the caval gradient had returned towards normal[8,36]. Another possible alternative, orthotopic liver transplantation, has achieved a 54 per cent 3-year survival rate[48] but hepatic vein rethrombosis is a recognized hazard[9,61].

Shunt patency can be usefully assessed postoperatively by Doppler flow studies of both the shunt and the portal vein (hepatofugal flow), contrast-enhanced CT scanning, magnetic resonance imaging and invasive angiography[55,62,63]. All patients in this series have maintained patent shunts to date. Experimental and clinical data suggest that the hepatic architecture can return towards normal after successful portosystemic shunting[12,22] but there is also a tendency for fibrosis to replace areas of liver cell necrosis[8].

In conclusion, this series of five patients demonstrates the effectiveness of the mesoatrial shunt in patients with the Budd–Chiari syndrome complicated by inferior vena caval obstruction or occlusion. There were no perioperative deaths and all shunts have subsequently remained patent. This success may be partly related to the choice of externally reinforced expanded PTFE for the prosthetic graft. The long-term patency of such shunts is likely to be a major factor in influencing the choice of therapy in the Budd–Chiari syndrome.

General practice-based population screening for abdominal aortic aneurysms: a pilot study

T. J. O'Kelly and B. P. Heather

Department of Surgery, Gloucester Royal Hospital, Great Western Road, Gloucester GL1 3NN, UK

Correspondence to:
Mr B P. Heather

All 1195 male patients aged between 65 and 74 years on the Family Practitioner Committee register for the four group practices in Stroud, UK were invited for a health screening check. The examinations included abdominal ultrasonography to measure maximum aortic diameter, measurement of blood pressure and recording of smoking habits. An attendance rate of 76 per cent was achieved (906 patients). Seventy-one patients (7·8 per cent) were found to have aortic diameters >2·5 cm and 14 (1·5 per cent) had aortic diameters >4·0 cm. Aneurysms were more common in smokers and in hypertensive patients. However, restriction of screening to patients with these risk factors would have led to a number of aneurysms remaining undiscovered. We recommend therefore that ultrasound screening for abdominal aortic aneurysms should be offered to all men between the ages of 65 and 74 years.

Keywords: Abdominal aortic aneurysm, ultrasound screening, population surveillance

Population screening for abdominal aortic aneurysms, with elective repair of the aneurysms so discovered, would prevent their rupture and reduce the number of deaths from this cause. Men between the ages of 65 and 74 years are recognized as a suitable target population, and an ultrasound-based programme for screening these individuals has been proposed[1]. To study this further, a pilot project of population surveillance in Stroud, UK was undertaken to look at the practicalities of screening, the distribution of aortic diameters and the relevance of risk factors such as smoking and hypertension.

Patients and methods

All men born in the years 1913–22 inclusive, residing in the Stroud area and appearing on the Family Practitioner Committee records of Stroud's four general practices, were invited for screening

Invitations in their names were printed on the general practitioner's notepaper and sent out informing the named recipient of conditions common in their age group, such as hypertension and vascular disease. It was suggested that these conditions could be detected by rapid, simple and painless means and that effective treatment could be offered. Each individual was given a specific appointment and all patients were screened at their own general practitioner's premises during afternoon or evening surgery hours. No attempt was made to follow up non-attenders

Screening was performed by a senior radiographer with special ultrasound training and a state registered nurse. Patients were seen at 5-min intervals and had their height, weight and blood pressure measured before abdominal ultrasound. Smoking habits were recorded

Ultrasonography was performed using a portable B mode grey scale machine and 3·5 MHz linear array probe (Philips SDR1200, Philips Ultrasound Incorporated, Santa Ana, California, USA) Hard copies were made of significant scans using a thermal imager Aortic measurement was taken from the outer margin of the anterior aortic wall echo (A) to the inner margin of the posterior aortic wall echo (P) and the maximum A–P diameter was recorded.

All examinations were completed within a 12-week period by holding three afternoon or evening sessions per week.

It was agreed before the study that all patients with an aortic diameter >4·0 cm would automatically receive an out-patient appointment with a consultant vascular surgeon (B P H) for consideration of elective surgery.

On the assumption that they represent a group with a high risk of future frank aneurysmal dilatation, subjects with aortic diameters between 2·6 and 4·0 cm have been entered into an ongoing study and will be seen again at 6-monthly intervals for repeated ultrasound examination Patients in this group were each given a careful verbal and written explanation of the findings and of our intention to send them a further appointment for repeat ultrasound examination

The χ^2 test was used with Yates' correction to compare patients for different risk factors.

Results

Records for the four participating group practices contained the names and addresses of 1195 men born in the years 1913–22 inclusive Of these, 906 attended for examination, an attendance rate of 76 per cent. Inaccuracies were found in the records which included a number of patients who had died or changed address. The true attendance rate of patients successfully contacted was in excess of 80 per cent.

Confident aortic diameter measurement was made in each of the 906 patients attending, and the findings are summarized in *Table 1*. Anteroposterior aortic diameters >2·5 cm were found in 71 patients (7·8 per cent) and 14 patients (1·5 per cent) had A–P diameters >4·0 cm. Aortic diameters >2·5 cm and >4·0 cm were discovered throughout the age range examined. There was no statistically significant difference in the incidence of large aortas between the younger and the older halves of the population examined. There appears to be a slight tendency for mean aortic diameter to increase with age, although this achieves statistical significance only when patients born in 1913 are compared with those born in 1922 ($P < 0{\cdot}02$, unpaired Student's t test).

Risk factors which might be used to select patients for aneurysm screening are examined in *Table 2*. Aortic diameters >4·0 cm were significantly more common in smokers ($\chi^2 = 5{\cdot}5$, $P < 0{\cdot}02$) and in patients with systolic blood pressure >180 mmHg ($\chi^2 = 4{\cdot}4$, $P < 0{\cdot}05$), although cut-off points of 90, 100 and 110 mmHg for diastolic pressure failed to demonstrate any significant difference in aneurysm incidence Of much greater practical importance is the fact that 6 of 14 aortas >4·0 cm were discovered in current non-smokers, 8 of 14 were in patients with systolic blood pressures <180 mmHg, and 7 of 14 were in patients with diastolic blood pressures <90 mmHg. Four patients with aneurysms were in low risk categories for all three criteria.

This paper was presented at the Annual Meeting of the Vascular Surgical Society of Great Britain and Ireland held in Leeds, UK on 24–25 November 1988

Discussion

This pilot study has demonstrated that large-scale population screening for abdominal aortic aneurysms is feasible and productive.

An attendance rate of approximately 80 per cent after a single invitation letter compares favourably with the best results from breast cancer screening[2] and is double that achieved in a previous population screening project for abdominal aortic aneurysms in which invitations and examinations were hospital based[3]. We have no doubt that the participation of general practitioners in both sending out invitation letters on their notepaper and holding screening sessions at their practice premises rather than in hospital has contributed significantly to the high attendance. The importance of the role of general practitioners in increasing attendance for screening has been shown previously[4]

The 1·5 per cent incidence of aneurysms suitable for consideration of elective repair shown in this study is somewhat lower than that found in other series. Nevertheless, we feel that the detection rate is both high enough to justify the implementation of a permanent district screening programme and low enough that the additional surgical workload could reasonably be accommodated within existing facilities.

All the examinations were carried out rapidly, efficiently and confidently by a nurse and a radiographer. Although one of the authors was present at each of the sessions, we have no doubt that future sessions could be organized without a doctor in attendance, thus keeping the cost of screening to a minimum

This study neither considers the fate of patients with aortic diameters between 2·6 and 4·0 cm nor does it establish if a normal aortic diameter measurement at the age of 65 or 66 years offers complete freedom from future risk of aneurysmal dilatation. These are important considerations in the design of a long-term screening programme.

A suitable population for aneurysm screening might be selected on the basis of known or presumed risk factors such as age, sex, smoking habits, hypertension or family history. Our study has been selective in screening only men, because of their significantly higher aneurysm risk, and in choosing an age group old enough to have an appreciable aneurysm incidence yet young enough to undergo elective repair. We have recorded only current smoking habits as admitted by the patient without biochemical confirmation and have taken a single blood pressure reading without details of antihypertensive medication. Within these, admittedly limited, definitions of smoking and hypertension, we have found aneurysms in non-smokers and in patients without high blood pressure. These aneurysms would have remained undetected had the selection criteria of smoking and hypertension been applied.

An aneurysm screening service can be run at reasonable cost by a nurse and a radiographer using inexpensive portable equipment and working without direct medical supervision. High attendance rates could be anticipated at screening sessions held at the invitation of general practitioners at their own health centre. Significant numbers of asymptomatic aneurysms would be detected and elective repair should reduce mortality from aneurysm rupture. Selection of patients for screening on the basis of smoking or hypertension is unnecessary and risks a proportion of aneurysms remaining undetected.

Acknowledgements

We particularly wish to acknowledge the contribution of Mrs L. Blandford and Mrs J. Cole, the senior radiographers who performed the ultrasound examinations, and of the various nurses from Gloucestershire Royal Hospital who carried out the remainder of the examinations.

This study would not have been possible without the help and co-operation of the 17 Stroud general practitioners, their secretaries, practice managers and receptionists.

This study was supported in part by a grant from the Gloucester Postgraduate Medical Centre Bursary Fund and by a donation from Meadox (UK) Ltd., Dunstable, UK

Nine post-Polya gastrectomy patients with symptoms of reflux gastritis were studied immediately before and 6 months after Roux-en-Y diversion with a 60 cm jejunal loop. Endoscopy, histology, HIDA radionuclide studies and acid secretory studies were performed to determine the effect of Roux-en-Y diversion. Symptomatic results were pleasing in that all patients were graded as Visick I or II. There was a statistically significant improvement in endoscopic evidence of mucosal damage (median score of 6 reduced to median of 1) and visible bile reflux (median score of 10·5 reduced to 0). Foveolar hyperplasia, superficial chronic gastritis and histological precursors of malignancy all improved. There was a significant decrease in the reflux of ^{99m}Tc-labelled HIDA into the gastric remnant while acid secretion remained unchanged. Roux-en-Y diversion with a 60 cm jejunal loop provides not only symptomatic relief but scintigraphic, endoscopic and histological evidence of pancreatobiliary diversion.

Keywords: Roux-en-Y diversion, reflux gastritis, symptoms, gastric histology, endoscopy, scintigraphy

Surgical diversion of the duodenal contents with a 60 cm Roux-en-Y loop is now the treatment of choice for patients with postgastrectomy reflux gastritis. Unfortunately the results of surgical diversion are often disappointing[1,2]. Unsatisfactory results may be due to poor patient selection, incomplete diversion of the duodenal contents or the complications of the procedure chosen to achieve surgical diversion.

Adequate surgical diversion should result in symptomatic improvement and also an improvement in the objective indices of reflux, namely endoscopic and histological appearances, and a reduction of enterogastric reflux as determined by HIDA (^{99m}Tc-Sn-2,6-diethylacetanilidoiminodiacetate) scanning. This paper addresses the problems of what constitutes adequate diversion.

Patients and methods

Patients

Nine patients (six men and three women) aged from 62 to 84 years (median 72 years) were studied prospectively immediately before and 6 months after a 60 cm Roux-en-Y diversion was performed for postgastrectomy reflux gastritis. All the patients complained of epigastric pain and bile vomiting after Polya gastrectomy 6–32 years previously. In all patients these symptoms could be provoked by instillation of the duodenal contents into the gastric remnant[3]. Three patients had a previous cholecystectomy before their gastrectomy and three had a truncal vagotomy either at the time of gastrectomy (one patient) or as a subsequent therapeutic manoeuvre aimed at resolving symptoms of reflux (two patients). Upper gastrointestinal endoscopy, gastric and oesophageal biopsy, pentagastrin acid stimulation tests and HIDA scans were performed before and 6 months after Roux-en-Y diversion.

Operation

A 60 cm Roux-en-Y jejunal loop was used to divert the duodenal contents. The afferent loop was divided at the stomach and reanastomosed end-to-side 60 cm distally along the efferent loop. In one patient a Tanner 19 modification was used. A truncal vagotomy was performed routinely.

Endoscopy

All the patients were endoscoped by two of the authors (M.J.H. and K.B.). K.B. was unaware of the diagnosis. We used an Olympus end viewing GIF Q gastroscope* with lecturescope teaching attachment which allowed independent but simultaneous assessment. Mucosal damage and evidence of visible reflux were assessed by each endoscopist. Indices of mucosal damage were erythema, hyperaemia, friability, granularity and contact bleeding. The extent of visible reflux was determined by the presence of waves of reflux across the stoma, bile pools between the rugae and bile staining of mucus.

Each endoscopist scored evidence of mucosal damage and visible reflux on a scale of 0–6 around the stoma and in the body of the stomach. These two scores were summed to give a mucosal damage and reflux score for each endoscopist. The two endoscopists' scores were then averaged to give a mucosal damage score and visible reflux score for the gastric remnant.

Histology

Biopsies were collected after each endoscopy. At least two random specimens were taken from the stoma and two from the gastric body. Additional biopsies were taken from any obviously abnormal area. Specimens were immediately fixed in 10 per cent formal saline, processed routinely and later stained with haematoxylin and eosin. Additional stains with Alcian blue/PAS and high iron-diamine/Alcian blue (HID–AB) were used to detect and classify intestinal metaplasia[4]. Histological changes were scored by I.M.F. and M.J.H. (I.M.F. was unaware of the diagnosis or the operative status of the patient) using a modification of a system used in previous studies[5].

Three categories of histological change were identified.

1. Foveolar hyperplasia is said to be the result of bile reflux and is characterized by elongation and tortuosity of the gastric pits[6]. We scored it as absent (0), mild (+), moderate (+ +) or severe (+ + +).

2. Superficial chronic gastritis may reflect injury and regeneration. It may be associated with an inflammatory infiltrate, pseudopyloric metaplasia, cystic degeneration and oedema, vasodilatation and infiltration of muscle fibres into the lamina propria. Like foveolar hyperplasia we scored it on a scale from 0 to + + +.

The foveolar hyperplasia and superficial chronic gastritis scores were combined (maximum = 6), giving a reflux gastritis score.

3. Possible precursors of malignancy; we recognized three features of mucosal morphology as suggestive of an increased risk of malignancy: chronic atrophic gastritis, intestinal metaplasia and dysplasia[7]. The definition and grading of dysplasia was based on the criteria outlined by Morson *et al.*[7].

Chronic atrophic gastritis was scored on a scale from 0 to + + +. Intestinal metaplasia was classified into three types on the basis of cell differentiation and the presence or absence of sulphomucin secretion[8]. If present it was scored as for chronic atrophic gastritis. The presence (score = 1) or absence of dysplasia was noted. A score indicating the extent of premalignant change (maximum = 7) was calculated.

Oesophageal biopsies were also collected from a point 5 cm above the gastro-oesophageal junction. Five features of altered oesophageal histology were noted: inflammatory cell infiltrates in the lamina propria, cellular atypia, haemorrhage, basal cell hyperplasia and elongation of the papillae. The first three features were noted to be present (score = 1) or absent. The basal zone should be less than 15 per cent of the total thickness of the epithelium[9]. If it exceeded 20 per cent the specimen was considered abnormal (score = 1). Papillary height was felt to be normal if the papillae extended over less than 50 per cent of the epithelial thickness but abnormal if between 50 and 75 per cent of the thickness (score = 1). If the papillae extended over more than 75 per cent of the epithelial span a score of 2 was recorded. This left a total possible score of 6.

Radionuclide scans

A dose of 200 MBq ^{99m}Tc-labelled diethyl HIDA was injected intravenously. An ^{111}In-labelled diethylenetriamine pentacetic acid (DPTA) fatty meal was administered 30 min later. If a cholecystectomy had previously been performed this time interval was reduced to 20 min. The fatty meal consisted of one sachet of Build Up®, 23 g Casilan® (Farley Health Products Ltd., Plymouth, UK), sugar to taste, 25 ml Prosparol® (Duncan, Flockhart and Company Ltd., Greenford, UK), 20 MBq ^{111}In-labelled DTPA and 300 ml water.

The fatty meal served to identify the gastric area of interest, instigate gallbladder contraction and provide a measure of gastric emptying. The patient was imaged using a large field of view γ camera set up to separate the photopeaks of ^{99m}Tc and ^{111}In using a narrow 12 per cent window. Immediately after finishing the meal the patient was positioned under the camera in a semi-recumbent position and the data were collected for 1 h at 1 frame/min using small area dual isotope acquisition.

Results were analysed by first drawing areas of interest over the stomach and over part of the right lobe of the liver. Activity–time curves were plotted for these regions separately for the two isotopes. The curves corresponding to the ^{99m}Tc photopeak window were corrected for crossover from the higher energy ^{111}In by subtracting a previously established constant fraction (0·51) of the ^{111}In curves.

The corrected ^{99m}Tc stomach curve was then further corrected to remove the effect of the left lobe of the liver. This was achieved by subtracting a multiple of the ^{99m}Tc liver curve from the ^{99m}Tc stomach curve such that the resultant curve was zero in the first frame. This manoeuvre was justified as long as there was no reflux in the first frame.

The area under the resultant, doubly corrected curve gave an indication of the quantity and duration of reflux of ^{99m}Tc-labelled bile into the gastric remnant over the duration of the test. This area was calculated using Simpson's formula as total counts per frame over 60 min using a dBase II® computer program (Ashton-Tate, Maidenhead, UK).

Acid secretory studies

Only eight patients agreed to a second pentagastrin test. After an overnight fast a 16 Fr nasogastric tube was passed with fluroscopic control into the gastric remnant. Basal acid output was collected in 4 × 15 min samples. A dose of 6 µg/kg of subcutaneous pentagastrin was given and a further 4 × 15-min samples collected. Three patients had a previous vagotomy and were given 12 µg/kg of pentagastrin. After Roux-en-Y diversion and truncal vagotomy all patients were given 12 µg/kg of pentagastrin. Samples were collected by continuous hand suction.

Anacidity was defined as a pH not less than 7 after stimulation with pentagastrin[10]. Basal acid output was calculated from the four basal collections. Peak acid output is said to represent the closest approximation to the maximum capacity to secrete acid[11]. It was calculated from the sum of the two highest consecutive samples[12]. All acid outputs were expressed as mmol/h.

Statistics

This population of patients probably does not conform to a 'normal' distribution and the median has been used as a measure of central tendency. The test of significance chosen was the signed rank non-parametric test as each patient acted as their own control.

Calculations were made using a Stats Plus® program (Human Dynamic Systems, California, USA) on an Apple IIe® computer (Model AZM 2010P, Apple Computer Company, Cupertino, California, USA).

Results

Operative results

All nine patients were pleased with the results of their operation and were graded as Visick Grade I or II. No patient had persistent pain or bile vomiting. Four patients had no complaints and a fifth was perfectly well until an adenocarcinoma of the prostate was diagnosed 18 months after his operation. Two of the other four patients had mild diarrhoea and two others occasionally experienced epigastric fullness and nausea. One patient was disappointed because he thought he had failed to gain weight although he had actually gained 2·8 kg. No patient had symptoms of sufficient severity to interfere with their lifestyle.

Endoscopy

The score for mucosal damage decreased from a median of 6 (range 1·5–10·5) to a median of 1 (range 0–3·5). Visible reflux also decreased from a median of 10·5 (range 1–12) to a median of 0 (range 0–4). Both these decreases were statistically significant ($z=-2{\cdot}43$, $P=0{\cdot}015$; $z=-2{\cdot}55$, $P=0{\cdot}011$, respectively).

The sum gastric endoscopic score also decreased from a median of 16 (range 2·5–22·5) to a median of 1 (range 0–7·5). This difference is statistically significant ($z=-2{\cdot}55$, $P=0{\cdot}011$).

Histology

Before Roux-en-Y diversion foveolar hyperplasia was present in the biopsies of all but one patient. The scores ranged from 0–3 with a median score of 1. After diversion foveolar hyperplasia was no longer seen in any of the biopsies. Superficial chronic gastritis improved in all patients. The median score decreased from 3 (range 0–3) to 1 (range 0–1). Overall the reflux gastritis score decreased from a median of 4 (range 3–6) to a median of 1 (range 0–1). This difference is statistically significant ($z=-2{\cdot}67$, $P=0{\cdot}007$).

Chronic atrophic gastritis also improved. Before Roux-en-Y diversion the scores ranged from 0–3 with a median of 1. After diversion chronic atrophic gastritis was less pronounced: the scores ranged from 0–1 with a median score of 1. Four of the nine patients had evidence of intestinal metaplasia before Roux-en-Y diversion. No patient had Type III intestinal metaplasia. Mild dysplasia was present in one patient. Intestinal metaplasia and dysplasia were not seen after Roux-en-Y diversion.

If the individual preoperative scores for the three possible precursors of malignant change were added together (maximum = 7), the scores ranged from 0 to 5 with a median of 2. After diversion the median score was 0 with a range of 0–1. This was a statistically significant improvement ($z=-2{\cdot}52$, $P=0{\cdot}011$).

The net oesophageal score ranged from 0–4 (median 3) before Roux-en-Y diversion but, postoperatively, improvement was noted in all except one patient. The range of scores remained 0–4 but the median score fell to zero. The difference reaches statistical significance ($z=-2{\cdot}38$, $P=0{\cdot}016$).

Prior cholecystectomy and vagotomy did not appear to influence the histological changes.

HIDA scans

Reflux of ^{99m}Tc-labelled HIDA into the gastric remnant decreased from a median of 2566 counts (range 631–15509) to a median of 58 counts (range 0–2926). This decrease (median 96 per cent) is statistically significant ($z=-2{\cdot}38$, $P=0{\cdot}017$).

Acid secretory studies

Three patients remained anacid after Roux-en-Y diversion and truncal vagotomy. There was no significant increase in basal acid output (median 0 mmol/h, range 0–0·73, $P=0{\cdot}59$) or peak acid output (median 0·55 mmol/h, range 0–4·94, $P=0{\cdot}68$) 6 months after diversion.

Discussion

The treatment of postoperative reflux gastritis remains a problem. The chances of a successful operative outcome range from 100 per cent to less than 60 per cent[2,13]. Evidence from animal experiments has demonstrated an association between gastritis and exposure to different enteric juices[14–18]. Subsequent surgical diversion of these juices improves the gastritis[19]. Such animal evidence offers strong theoretical support for the use of surgical diversion of duodenal contents in the treatment of postoperative reflux gastritis in man.

The results of subsequent patient studies are contradictory. Although the presence of duodenal contents in the gastric remnant may evoke a symptom response[3,20], there is no clear association between endoscopic and histological findings and symptoms after gastrectomy. Subsequent surgical diversion may improve both symptoms and the endoscopic appearance[13,21–24]. Our study has confirmed these findings.

Hoare *et al.*[22] have suggested that reflux causes the gastric mucosal erythema seen endoscopically in patients with reflux gastritis. Our study supports this finding. Endoscopic evidence of mucosal damage including erythema and visible reflux improved significantly after Roux-en-Y diversion.

The histological response to Roux-en-Y diversion remains controversial. This study, and others, have demonstrated that foveolar hyperplasia will regress in man and animals after diversion of the duodenal contents[19,24]. As in a previous study[25] this effect was independent of vagotomy in our patients.

Gastritis, which is an almost universal finding after gastrectomy[26–29], was seen to improve after Roux-en-Y diversion in our study and one other[30]. This is contrary to most previous work[22,24,31]. The length of follow-up in our study is no different from other studies where follow-up ranged from 3 to over 12 months. We did not take fewer biopsies than other studies and our data are thus no more prone to sampling errors Day-to-day and individual variations in reporting mucosal changes were also considered and the histology of eight random patients was re-reported firstly by I.M.F. and then by another histopathologist without significantly altering our findings

There are two other possible reasons which might explain the difference between our results and those of other published series. One may be the adequacy of surgical diversion and the other might be the specific features of gastric mucosa as studied by different authors.

There is an increasing body of evidence demonstrating a strong correlation between high concentrations of intragastric bile acids and mucosal abnormalities including gastritis[30,32,33]. Most previous work has concentrated on the inflammatory aspects of gastritis. Recently Dixon *et al.* have described 'reflux' gastritis as being characterized by foveolar hyperplasia, a paucity of inflammatory cells, oedema, increased numbers of smooth muscle fibres, and vasodilatation in the lamina propria[34]. Our work has been in progress since 1982 as long term follow-up was required. However, our system of scoring is not unlike that of Dixon *et al* [34]. In all patients in whom reflux was abolished the features of reflux gastritis resolved. This finding would support the conclusion of Dixon and colleagues that reflux gastritis is a distinct pathological entity[34]. Furthermore it explains why such variable results have been reported on the effects of Roux-en-Y diversion on the gastric mucosal morphology.

If histological evidence of reflux gastritis is to decrease, surgical diversion of the pancreatobiliary secretions must be adequate. In those studies where there was no histological improvement the length of Roux-en-Y loop chosen to achieve surgical diversion was usually less than 50 cm[22,24,31]. In our patients, using a 60 cm loop, there was also convincing endoscopic and scintigraphic evidence that adequate surgical diversion had been achieved.

Chronic atrophic gastritis, intestinal metaplasia and dysplasia may be significant features of premalignant change[7]. Gastric mucosal atrophy may be found in a healthy population[35] but enterogastric reflux is probably the most important factor in its pathogenesis[36]. If so, diversion of the enteric contents should lead to an improvement of gastric mucosal morphology. Some support for this hypothesis may be found in a case report from Bristol[37] where a patient with almost complete achlorhydria secondary to enterogastric reflux was treated with antrectomy and Roux-en-Y diversion. Normal acid secretion had returned 4 months later. Conversely a study from Belfast[31] failed to show any improvement in atrophic gastritis after Roux-en-Y diversion. The authors did not state the length of their loop, though a previous study from the same unit[38] used an 18–40 cm Roux-en-Y loop In our patients, using a 60 cm loop with a scintigraphically proved reduction in HIDA-labelled reflux, chronic atrophic gastritis appeared to be less extensive after Roux-en-Y diversion.

Another possible explanation may be the definition of what constitutes gastric atrophy. Watt *et al.*[31] scored atrophy as a loss of specialized cells. We included other features of the mucosal morphology including cystic degeneration, chronic inflammatory infiltrate and intestinal metaplasia.

A further factor may be the presence or absence of a gastric antrum. Independently, Lawson[39] and Witt *et al.*[18] have shown that antrectomy leads to epithelial hypoplasia in dogs. In turn, reflux of the duodenal contents damages this epithelium and the subsequent gastritis is more severe than in animals with an intact antrum. Watt *et al.*[40] detected some differences in the effect of Roux-en-Y diversion (no antrum) compared with closure of a gastrojejunostomy (antrum intact). All our patients had a prior antrectomy. Five of the nine patients had varying degrees of gastric atrophy. There was no correlation between the degree of atrophy and the time span after gastric surgery. After diversion of the duodenal contents the gastritis and the atrophic appearance of the mucosa improves. This result implies that gastric atrophy may be reversible, even in the presence of antrectomy, if the damaging agent is withdrawn.

Intestinal metaplasia may be an advanced stage of chronic atrophic gastritis[41] but only one type, Type III, may be premalignant[42]. In our study no patient had Type III intestinal metaplasia. Although four patients had evidence of intestinal metaplasia in their pre-Roux-en-Y biopsy, none showed intestinal metaplasia after diversion. This is a new finding but is compatible with Tympner *et al.*'s[43] conclusion that intestinal metaplasia is associated with increased reflux. It may also be explained by the small size of our series or a sampling error. With this in mind we reviewed the gastric histology of five other post-Roux-en-Y diversion patients who we had not studied prospectively. None of these patients had intestinal metaplasia.

Dysplasia is also frequent after gastrectomy[27,29,31,44,45]. Its severity may be correlated with scintigraphic evidence of duodenogastric reflux[45]. The apparent frequency of dysplasia, however, may be misleading as it is easily confused with foveolar hyperplasia[34]. Only one of our patients, had evidence of dysplasia and this precludes a useful contribution to this debate.

Whether duodenogastric reflux causes postgastrectomy gastric cancer or not remains controversial. Adequate Roux-en-Y diversion, in our patients, appeared to reduce the extent and severity of many of those histological changes considered by some to be precursors of malignant change. Time after diversion does not appear to influence the mucosal changes noted As mentioned previously, we studied five other patients up to 3 years after Roux-en-Y diversion and all appeared to have relatively normal gastric mucosa. More patients need to be studied using a Roux-en-Y loop of sufficient length to ensure adequate diversion of the duodenal contents if this question is to be resolved.

Oesophageal histology in our patients improved after diversion of the duodenal contents as it did in the study by Hoare *et al.*[22]. Ismail-Beigi *et al.*[9] have suggested that the histological features of oesophagitis – papillary elongation and basal cell hyperplasia – are features of increased cell loss and replacement following desquamation of the superficial layers of the epithelium by reflux of the gastric contents. Their patients were refluxing acid, but bile and trypsin have also been shown to have a toxic effect on the oesophageal mucosa[46,47,48] and represent the probable mechanism of injury in our patients Adequate diversion of bile led to a marked improvement in these histological features of mucosal damage.

A 60 cm Roux-en-Y afferent loop diversion successfully reduced ^{99m}Tc-labelled HIDA bile reflux into the gastric remnant Excellent symptomatic relief was accompanied by endoscopic and histological evidence of a return towards normal in the gastric remnant.

The historical background, aetiology, clinical features, radiographic findings and treatment of abdominal lymphangiomas are reviewed. The condition may give rise to the acute surgical abdomen.

Keywords: Retroperitoneal lymphangioma, acute surgical abdomen

Intra-abdominal cystic and cavernous lymphangiomas are rare benign tumours, usually found incidentally through lymphangiography, during elective abdominal surgery, in an acute surgical abdomen, or at post-mortem examination. The incidence of such tumours has been estimated to range from 1 per 27 400 to 1 per 100 000 hospital admissions[1–3].

Historical background

Braquehaye[4] credited Benievine, a Florentine anatomist, as being the first to note a mesenteric cyst during a post-mortem examination in 1507. Slocum[5] has stated that the earliest description of a chylous cyst, found at necropsy, was published by Rokitansky in 1842. Millard and Tillaux[6] in 1880 were the first to report on the successful treatment of a patient with a mesenteric cyst. According to Walker and Putnam[1], omental cysts were not described until Gairdner's report in 1852. This type, which is believed to be less common than mesenteric cysts, has been estimated to occur from three to ten times more frequently[1]. Pean in 1883, as quoted by Slocum[5], was the first surgeon to record the recovery of a patient who had a lymphangiomatous cyst treated by marsupialization. The initial American report of a chylous cyst of the mesentery was presented by Carson in 1890[7]. Some years later, Sarwey[8] successfully excised a unilocular chylous cystic lymphangioma located in the region of the head of the pancreas of a 9-year-old girl Gaudier and Gorse[9] in 1913 surveyed the accumulated relevant literature, and included a 4-year-old patient of their own with a mass in the right lumbar region which was excised successfully. They claimed this to be the first description of a case of retroperitoneal cystic lymphangioma to appear in print. In 1941 Loeb[19] reviewed the literature on mesenteric cysts and estimated that reports on 550–600 patients had been published. Bearhs *et al.*[11], reporting from the Mayo Clinic, found only nine cases undergoing surgery between the years 1911 and 1947. Pack and Tabah[12], discussing over 870 patients with primary tumours of the retroperitoneum, including 120 of their own, found only five with cystic tumours. Harrow[13] estimated that of more than 600 patients with mesenteric cysts, 70 of whom had retroperitoneal cysts, only 14 fitted the criteria for lymphatic cystic tumours. Rauch[14] screened the literature and added two male patients aged 17 and 10 years with retroperitoneal lymphangiomas. Henzel *et al.*[15] gave an excellent overview of the published material on intra-abdominal lymphangiomas, while adding a 20-year-old patient treated by them.

Aetiology

Sabin[16] divided the development of the lymphatic system into two stages:

1. The primary stage which encompasses the development of isolated lymph sacs derived from veins that are united by the thoracic duct
2. The second stage, which involves peripheral growth of lymph vessels that sprout from the endothelial lining of the sacs. The lymph sacs are transformed into a plexus of lymphatic capillaries by bridging of the lumen with bands of connective tissue from which chains of lymph nodes are derived.

Numerous theories have been proposed concerning the origin of cystic lymphangiomas. Barnett and Branch[17] summarized these theories on the following aetiological basis:

1. Retention, which explains the lymphangioma on the basis of mechanical pressure
2. Disturbance of the endothelial secretory function of the vessels or of endothelial permeability
3. Inflammatory background
4. Embryonal origin.

The last theory, favoured by Barnett and Branch[17], explains the lymphangioma on the basis of a defect in embryonal organization of the lymphatic system. Some investigators express the opinion that retroperitoneal lymphangiomas arise from obstruction of existing lymphatic channels by an inflammatory fibrotic process or lymphatic hamartoma[18]. In general, the majority of authors subscribe to the last two theories.

Godart[19] believes that the aetiology is related to an abnormal development of the lymphatics in that there is failure of communication of a branch, or branches, with the central system, thus explaining why cystic lymphangiomas are found in the same position as fetal lymph sacs (cervical, mediastinal and retroperitoneal). He proposed that lymphatic spaces in the embryo fail to join the venous system, thus producing cysts. Elliot *et al.*[20] believe that lymphaticovenous shunts exist in the perinodal tissues as congenital deficiencies, their formation resulting in cysts.

Other suggested aetiologies include failure of the leaves on the mesentery to fuse or localized degeneration of lymph nodes[2]. Trauma has also been offered as a possible cause of lymphangioma[21,22].

Ewing[23] stated that retroperitoneal lymphangioma occurs in both children and adults as cystic tumours, originating along the spinal column and ramifying into the pelvis behind the kidney or colon, upward to the liver and spleen, as well as into the omentum. He included in this entity a variety of slowly growing congenital tumours of the skin and subcutaneous tissue, neck muscles, axilla, trunk, lip, tongue, eye and orbit.

Lymphangiomas that arise in the retroperitoneal space

0007–1323/89/050485–05$3.00 © 1989 Butterworth & Co (Publishers) Ltd

separate the leaves of the mesentery as they grow anteriorly and take up a mesenteric position, or they may push posteriorly in their development, to be recognized only as retroperitoneal tumours. They may encroach on the adjacent structures, including gastrointestinal organs, and so lead to partial obstruction.

Occasionally it is impossible to distinguish between retroperitoneal lymphangiomas and mesenteric cysts, as both these tumours may extend from the retroperitoneum into the mesentery[24] and, moreover, also have the same gross appearance. With these difficulties in mind, Takiff *et al.*[25] stressed the importance of differentiation between these two lesions in view of the fact that lymphangiomas often behave in an aggressive manner and invade the adjacent structures. They observed that lymphangiomas are principally a disorder of childhood and young adulthood, while mesenteric cysts may occur at all ages, although they are mainly found in the fourth decade of life.

Histologically, these two lesions differ. Cystic lymphangiomas display a single endothelial lining, foam cells, innumerable lymphatic channels between lobules of adipose tissue, fibrous and lymphoid tissue, blood vessels and smooth muscle[13,26]. The lining cells of the mesenteric cysts, on the other hand, are often cuboidal or columnar or, on rare occasions, may even be entirely absent.

While lymphangiomas are histologically benign, two patients with lymphangioendotheliomas have been reported[11]. Malignant lymphangiomas are known as lymphangiosarcomas[27]. A unique case of a retroperitoneal malignant tumour in a 44-year-old man has been described recently[28]. The tumour had infiltrated the duodenum and the head of the pancreas, and pancreatoduodenectomy was performed[28].

Classification

Lymphangiomas are classified primarily on a histological basis. The original classification established by Wegner in 1877[29], which is still considered to be the most reliable one[13,14,17,30–34], divides lymphangiomas into simple, cavernous or cystic tumours.

The simple form represents a new growth of small lymphatic channels lined with endothelium, usually situated superficially in the skin. This type consists of an ill-defined mass composed of dilated lymph vessels with rich cellular connective tissue stroma. It has a moderate number of channels through which it is connected to the adjacent lymphatic system.

The cavernous type comprises communicating lymph-filled locules separated by septa and found chiefly in macroglossia, macrocheilia and, more rarely, in other parts of the face and skin. This kind of lymphangioma is a spongy, compressible tumour with dilated lymph vessels and lymphoid stroma, having a moderate number of channels which connect it to the normal lymphatic system.

The cystic type may be uni- or multilocular and appears mainly in the neck, breast, axilla, lower sacral region, abdomen, thighs and inguinal region. When located in the mesentery, cystic lymphangiomas often contain chyle and are appropriately termed chylangiomas or 'chylous cysts'. The tumour is composed of one or many variously-sized cysts ranging from 1 mm to 5 cm in diameter, often communicating with each other[35], and lined with endothelium. The cyst may contain clear chylous, serous, bloody, purulent or chocolate-coloured fluid. Such cystic tumours have practically no connection with normal adjacent lymphatics. They may arise from cavernous forms in which one compartment enlarges, breaking the septa and compressing the other compartment[13]. Gerster[36] maintains that it is not always possible to draw a sharp line between cystic and cavernous lymphangiomas, since the former may contain areas that are cavernous in structure.

Henzel *et al.*[15] attempted to outline some features which will permit differentiation between the three types (*Table 1*). Two entries listed in *Table 1* warrant emphasis: (1) only cavernous and cystic lymphangiomas have been found in the retroperitoneum, and (2) only in the cavernous and cystic types does lymphangiomatous malignant degeneration occur.

Lymphangiomas most commonly manifest themselves in the neck (75 per cent), when they are called cystic hygromas. The rest are found mainly in the axillary region (20 per cent), while the remaining 5 per cent may appear at various sites in the body, among which are mediastinum[37,38], lungs[39], chest wall, arms, back, parotid, spleen[40–42], liver[43], uterus[44], rectum[45], inguinal region[46], and multiple other sites[33]. Skeletal involvement may be seen as part of a generalized lymphangiomatosis[43,47,48]. In the spleen[49], as in the stomach and omentum[50], the lymphangioma may be associated with intramural gastric pancreas. It may also be found in the oesophagus and stomach[51,52] and in the jejunum[53].

Less than 1 per cent of lymphangiomas are found in the retroperitoneum, those occurring in the mesentery and omentum being called mesenteric and omental cysts, respectively[21,22,33,34,47,54]. Most unilocular lymphangiomas are localized within the mesentery or the omentum, whereas

Table 1 *Differential features in the gross and microscopic characteristics of lymphangiomas (according to Henzel* et al.[15]*)*

	Simple	Cavernous	Cystic
Anatomical location	Skin and subcutaneous tissue of face and neck	Cheek, tongue, buccal tissue, neck, retroperitoneal	Neck (hygroma), axillae, inguinal area, retroperitoneal
Compressibility (patent to adjacent normal lymph flow)	Yes	Yes	No
Unilocular/multilocular	Unilocular	Both	Both
Serous and chylous variants	No	Yes	Yes
Origin congenital	Yes	Yes	Yes
Encapsulated	No	No	No
Microscopic dilated lymphatic spaces	+	++	++ to +++
Endothelial lining within spaces	Yes	Irregularly occurring	Irregularly occurring
Inflammatory cell infiltration	Insignificant	++	++ to +++
Smooth muscle component	Very infrequent	Yes	Yes
Frequency of foam cell	No	+	++
Benign growth	Slow, if at all	Yes	Yes
Potential for malignant transformation	Unknown	Rare but substantiated	Possible

+, Mild, ++, moderate, +++, substantial

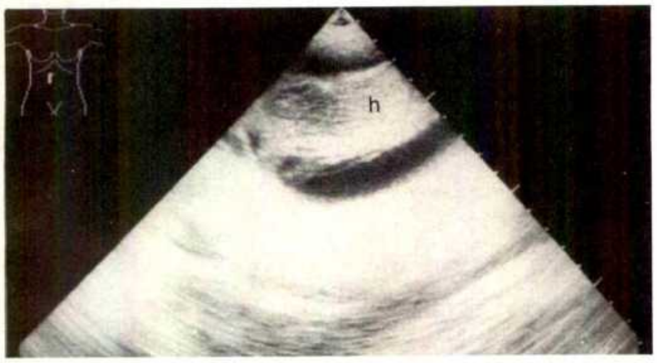

Figure 1 *Real-time ultrasound image showing a portion of the large cystic loculated mass situated in the left upper abdomen with an echogenic structure within the lesion representing the intracystic haemorrhage (h)*

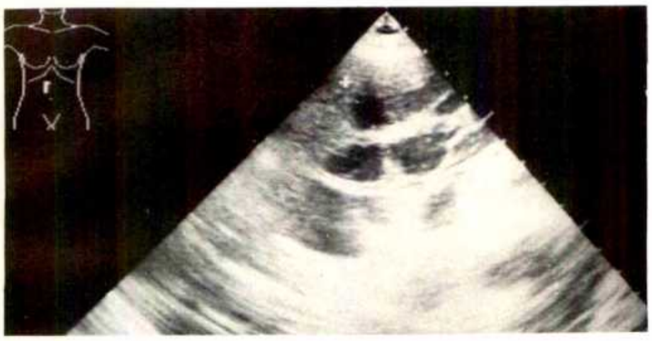

Figure 2 *Real-time ultrasound image showing smaller cystic areas situated in the epigastric region which were part of the large multiloculated mass*

the multiloculated variant may occupy the entire bowel, mesentery and much of the retroperitoneal space.

Clinical features

Retroperitoneal cystic lymphangiomas usually appear in early infancy with about 90 per cent being detected in the first 2 years of life[35]. Except for the series of Takiff *et al.*[25] no sex predilection has been observed. These authors describe 28 patients, eight of whom had cystic lymphangiomas and 20 of whom had mesenteric cysts. Of the eight cystic lymphangioma patients, six were symptomatic; four of the eight patients were found on examination to have ascites and large lesions (mean diameter 8·8cm). Of the 20 patients with mesenteric cysts, six were male, and only five of the entire group of 20 were symptomatic. None of them had ascites, and the lesions were smaller than in the group with lymphangiomas (mean diameter 4·7 cm). There were no clinical features which served to differentiate retroperitoneal lymphangioma from other retroperitoneal masses.

The most common clinical manifestation of retroperitoneal cystic lymphangioma is that of a palpable, soft, cystic mass in the abdomen, which usually enlarges slowly. Some patients may complain of a 'dragging' sensation[15], while others may be asymptomatic, the mass being discovered only incidentally during examination for an unrelated complaint. Like most retroperitoneal masses, these, too, remain occult until pressure occurs, or the mass has become visible or palpable. Pressure symptoms depend largely on the location of the cystic mass, and in 40 per cent of cases pressure on the adjacent structures may cause partial intestinal obstruction[15], displacement of kidneys and ureters to the midline[31], ureteric obstruction[30,55] and displacement of the middle colic artery[56].

The cyst seldom causes acute clinical symptoms and, as the retroperitoneum is relatively inaccessible to physical examination, the diagnosis is often entirely accidental. When acute symptoms do occur, they are due either to pressure on the adjacent structures by the enlarging mass, or to complications, such as haemorrhage into the cyst, inflammation of the cyst wall, infection, perforation, torsion and rupture[17,57,58]. The patient may suffer from abdominal pains and tenderness with guarding and fever; leukocytosis may be present. These cases of acute clinical abdomen may mimic appendicitis, as occurred in 12 per cent of the patients reviewed by Galifer *et al.*[59].

In our own practice we have treated a 25-year-old woman with a large upper mid-abdominal cystic multiloculated mass (*Figures 1* and *2*), and a 20-year-old woman with mesenteric cystic lymphangioma (*Figure 3*). Both patients presented with abdominal pain and fever (38°C) and complained of vomiting. On physical examination, psoas and Rovsing's signs were positive. They underwent laparotomy and excision of the cysts. *Figures 4* and *5* demonstrate the histological findings in these two patients.

Most of the cases reported in children also mention an acute surgical abdomen[37,54,60]. Coagulation disorders described in lymphangiomatosis[39] included features of consumptive coagulopathy[61].

A useful list of conditions to be considered in the differential diagnosis of lymphangioma has been compiled by Blumhagen *et al.*[62] (*Table 2*).

Radiographic findings

Previously, the diagnosis of lymphangioma was made during surgery or at autopsy. Currently, we have access to methods

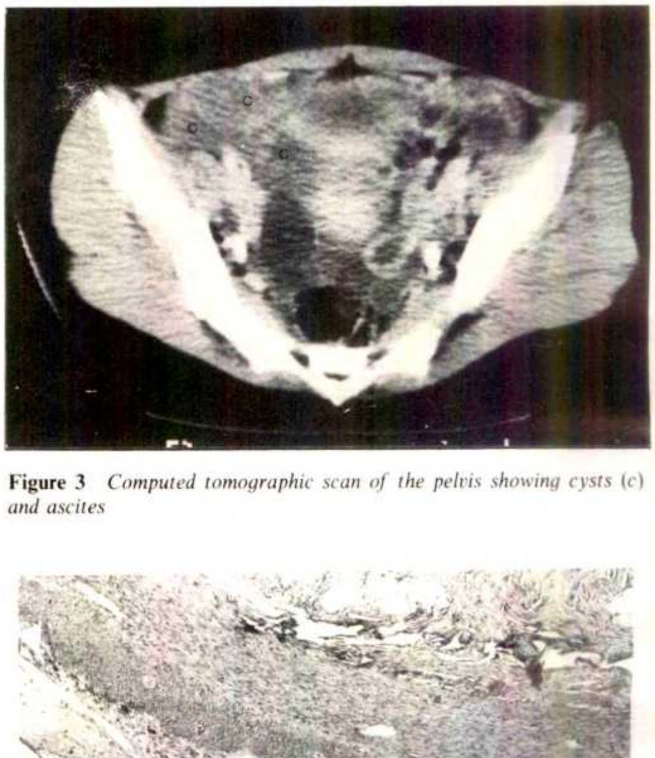

Figure 3 *Computed tomographic scan of the pelvis showing cysts (c) and ascites*

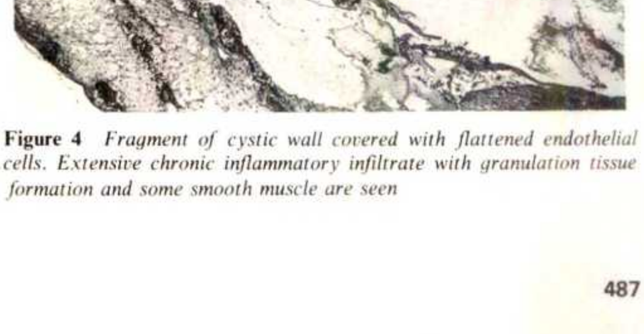

Figure 4 *Fragment of cystic wall covered with flattened endothelial cells. Extensive chronic inflammatory infiltrate with granulation tissue formation and some smooth muscle are seen*

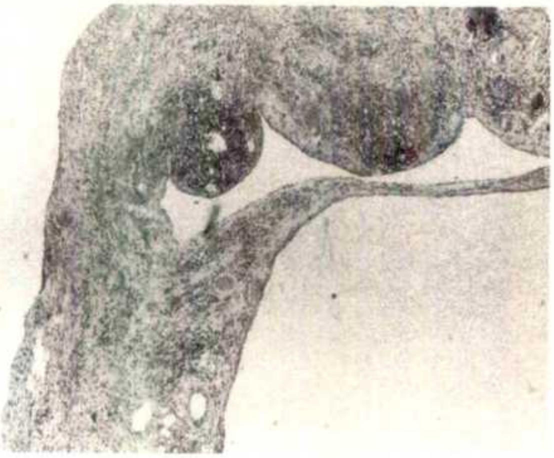

Figure 5 *Cystic lymphangiectasis beneath the serosal surface of the appendix*

Table 2 *Differential diagnosis of lymphangioma (according to Blumhagen* et al.[62])

- Huge lesions
  - Ovarian:
    - Teratoma
    - Cystadenoma
    - Mucinous cystadenoma
  - Pancreatic pseudocyst
  - Multilocular cystic nephroma
  - Lymphoma (not truly cystic)
- Lesions of moderate size
  - Haematoma
  - Postoperative seroma
  - Peritonitis
  - Echinococcal cyst
  - Enteric duplication
  - Lymphoma (not truly cystic)
  - Kidney:
    - Polycystic kidney disease
    - Cystic dysplasia
    - Clear cell sarcoma
  - Spleen:
    - Epidermoid cyst
  - Liver:
    - Mesenchymal hamartoma
    - Cystic hepatoblastoma
    - Haemangioendothelioma
    - Choledochal cyst
    - Carolis disease
    - Embryonal sarcoma

of imaging that afford a preoperative diagnosis. Radiographs may be helpful in localization through displacement of surrounding viscera, and calcification has been described in a cavernous pancreatic lymphangioma[63]. Asch *et al.*[43] reported on a calcified cystic lesion in the spleen of a child with diffuse involvement of the liver.

Intravenous urography may be of value in revealing displacement of the kidney or ureters. A barium enema may demonstrate medial or lateral displacement of the ascending or descending colon without obstruction, while barium studies of the duodenum may assist in the diagnosis of a lymphangioma arising in the upper abdomen.

Other diagnostic imaging methods have proved of value in preoperative localization of these masses and in defining their internal architecture. Ultrasound contributes to the diagnosis of lymphangioma by showing a cystic mass with multiple thin septa. This mode of examination also shows the relationship of the mass to abdominal and retroperitoneal structures[62].

The computerized tomographical features of cystic lymphangiomas are uni- or multilocular massses of water density (*Figure 3*). The wall of the mass may be enhanced following intravenous administration of contrast material. The septa are of uniform thickness[32]. In one case, the computed tomograpical attenuation of 15 Hounsfield units within the cyst suggested the presence of fat within the lesion[34].

Although the efficacy of magnetic resonance imaging in displaying the cystic lesion is comparable to that of computed tomography, the signal intensities and T-1 and T-2 values, which differ between cysts, may reflect differences in the composition of cystic fluids[30].

With lymphangiography, only those lymphangiomas that communicate with the lymphatic system are directly visualized. A cystic lymphangioma of the mesentery (mesenteric cyst), which was shown to communicate with the thoracic duct, demonstrated dilatation of interconnecting lymphatic channels with passage of contrasting material into the mesenteric cystic spaces on lower extremity lymphangiography[64].

Angiography clarifies the manner in which the mass causes displacement of arterial branches, as well as stretching of an artery by the tumour, although the method does not show tumour vascularity.

Of the methods noted here in brief we advocate ultrasound and computed tomography as the most efficacious procedures for visualizing abdominal lymphangiomas.

Treatment

Complete excision is the treatment of choice and it is usually carried out with relative ease. Aspiration of the larger cysts lessens the difficulty with exposure. If the cyst has invaded an abdominal organ like the small bowel, spleen or the tail of the pancreas[25], total excision with resection of the involved organ is indicated. In the past, both external and internal marsupialization were performed. Although cystenterostomy has been suggested, the form of drainage preferred was internal peritoneal cavity marsupialization. Such surgical forms of treatment have become obsolete, and the modern approach advocates total excision of the mass in a patient with cystic retroperitoneal lymphangioma. With incomplete removal of the cyst, there is a possibility of recurrence at a later date, such as was observed by Raszkowski *et al.*[65] 7 years after the original surgical intervention.

Conclusions

The historical review demonstrates the relative rarity of cystic abdominal lymphangioma. The aetiology of the lesion is probably a primary malformation of the lymphatic system, essentially a hamartoma, which may either grow continuously, or cause blockage and subsequent enlargement of lymphatic channels.

Histologically, lymphangiomas can be distinguished into simple, cavernous and cystic types. The clinical features are typically those of a space-occupying lesion causing pressure on adjacent structures or of complications within the lesion itself. The patient often presents with an acute surgical abdomen. Ultrasound is the imaging modality of choice, owing to the cystic internal consistency. Other imaging modalities, especially computerized tomography, may be useful. The recommended treatment is complete excision.

Gastric banding in the treatment of morbid obesity

R. M. Kirby, T. Ismail, M. Crowson and R. M. Baddeley

Department of Surgery, General Hospital, Steelhouse Lane, Birmingham, B4 6NH, UK

Correspondence to:
Mr R. M. Baddeley

Gastric banding was carried out in 30 patients as a treatment for morbid obesity. The mean excess weight lost at 3 months was 32·6 per cent (27 patients) and 69·7 per cent at 2 years (eight patients). Fifteen patients required 22 reoperations for technical complications. Two patients underwent removal of the band and seven patients were converted to a stapled vertical Silastic® ring gastroplasty. Although gastric banding appears to be a satisfactory method of achieving weight loss, the complication and reoperation rates are unacceptable in our hands. It is recommended that this operation should no longer be used as a treatment for morbid obesity.

Keywords: Morbid obesity, gastric banding, weight loss, complications

Bariatric surgery, the surgery of morbid obesity, has been revolutionized by the introduction of gastroplasties. These procedures have been pioneered by Gomez[1] using the horizontal gastroplasty and Mason *et al.*[2] using the vertical banded gastroplasty. Other techniques, e.g. gastric partitioning with gastrogastrostomy and gastric partitioning with removal of staples to create a stoma[3], have failed to achieve satisfactory long-term results. We have randomly compared two groups of patients undergoing vertical Silastic® (Dow Corning, Reading, UK) ring gastroplasty and horizontal gastroplasty and found that, although good weight reduction was achieved with both, the reoperation rate was high with horizontal gastroplasty and this technique was subsequently abandoned[4]. An alternative gastroplasty, gastric banding (the separation of the stomach into two compartments by a band passed around the upper part of the stomach) has been reported to be a simple, cheap and effective form of gastroplasty. A small trial was therefore commenced in 1985 and our experience is reported here.

Patients and methods

After investigations to exclude endocrine abnormalities and other causes of obesity, and after psychological assessment, 30 patients referred for treatment of morbid obesity were assigned to the trial of gastric banding. The majority were women (male:female ratio 5:25). The mean age was 37·7 years (range 24–54 years). The mean weight of the patients was 134·7 ± 30·4 kg and the mean body mass index (weight in kilograms/height in metres^2) was 50·8 ± 9·1.

All operations were carried out by one surgeon (R.M.B.). Laparotomy was performed through an upper abdominal midline incision with the table tilted 45° (foot down). After minimal dissection of the lesser curvature and fundus a Dacron® or Teflon® (E.I. du Pont de Nemours and Company, UK) band was passed around the upper part of the stomach, tightened and sutured into place to provide a 50-ml proximal compartment and a 1·2-cm diameter stoma into the distal stomach[1,5]. The proximal and distal compartments were sutured to each other, lateral to the band, to prevent it from slipping (*Figure 1*). Postoperatively the patients were commenced on an 800-calorie liquid diet and converted to solid food at 6 weeks.

Patients were followed up at 1 month and then at 3-monthly intervals after operation. They were assessed objectively by the measurement of the weight loss and the representative percentage of excess weight lost based upon Metropolitan Life Assurance tables[12] and reduction of mean body mass index. Not having available an objective method of assessing proximal compartment volume, a crude subjective guide was obtained by asking each patient to estimate whether the size of meals that she or he could eat could be served on a saucer, tea plate, dessert or dinner plate. Haematological and biochemical parameters were checked at each visit.

Results

Patients were followed up for between 6 months and 2 years. Two patients had the banding reversed 7 and 19 months after initial surgery. A further seven patients were converted to vertical gastroplasties at a mean of 17 months (range 10–25 months, see below) and seven were lost to follow-up. Nineteen patients would have been eligible for follow-up at 2 years although only eight could finally be assessed after non-attenders (five) and those being reversed or converted (six) were removed.

Weight loss

One patient was withdrawn from the study because during operation the upper stomach could not be fully visualized owing to the grossly excessive obesity (223·6 kg). Although gastric banding was carried out, the size of the proximal compartment was not fully controlled. His weight loss was minimal, with only 13·4 per cent of his excess weight being lost after 2 years.

The loss of excess weight and reduction of body mass index (weight in kilograms/height in metres^2) of the remaining patients are outlined in *Tables 1* and *2*. It can be seen that the majority of weight was lost in the first 12 months, although it continued for 18 or 24 months in some.

Subjective pouch assessment (Figure 2)

Twenty-four patients assessed the size of their meals at 3 months and ten at 2 years (this included a patient who was not included in the weight assessment, and a non-attender who was quizzed by telephone but was unable to give her present weight).

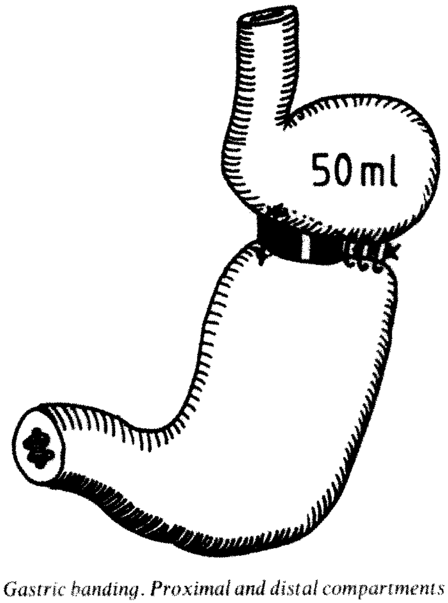

Figure 1 *Gastric banding. Proximal and distal compartments are sutured to each other lateral to the band to prevent it from slipping*

Table 1. *Percentage of excess weight lost*

Time (months)	No. of patients	Mean	Standard deviation	Minimum	Maximum
3	27	32·6	12·2	6·4	54·5
6	25	49·7	15·6	25·4	85·4
12	23	54·4	24·4	0	96·5
18	16	60·2	32·8	4·7	129·5
24	8	69·7	27·7	20·7	103·0

Table 2 *Changes in mean body mass index*

Time (months)	No. of patients	Mean	Standard deviation
Before operation	29	50·8	9·1
3	27	43·1	9·1
6	25	38·8	9·2
12	23	37·5	9·8
18	16	35·0	8·8
24	8	36·8	12·3

Body mass index = weight in kilograms/height in metres^2

Thirteen of the original 24 patients were able to eat only a saucer-sized meal 3 months after operation, whereas only one of the final ten patients was eating meals this small. Seven of these patients had noticed an increase in pouch size, although only three of them had been taking saucer-sized meals initially. Eighteen patients in total noticed an increase in the size of meals they could take. Two patients reported a decrease in meal size and five did not report any change. (One patient missed the 3-month assessment.)

Complications and reoperation

There were no deaths as a result of surgery and no later deaths. Seventeen patients required reoperation but two of these were for cosmetic reasons (abdominal apronectomy) and were, therefore, not considered further. Of the remaining 15 patients, two had three reoperations and three had two reoperations, giving a total of 22 reoperations.

Four patients required surgery because the band was too tight. Two patients simply had the bands removed because of severe vomiting, one of them occurring a month after reoperation for intussusception (see below). One patient had the banding revised and one had the banding converted to a vertical stapled Silastic® ring gastroplasty.

Seven patients required further surgery because the banding was too loose or ineffective. The banding was revised in five patients, and converted to a vertical gastroplasty in three. One patient in the latter group had two operations.

Four patients developed an intussusception of the distal gastric compartment into the proximal. Barium meal radiographs had suggested volvulus at the site of the band, although there was no evidence of this at reoperation. The banding was simply revised in three patients but was converted to a stapled gastroplasty in two of these patients and in the fourth patient. Two of the latter patients were those undergoing three reoperations: two reoperations in each case were for intussusception. One of the patients simply undergoing revision needed to have the band removed 1 month later because of extreme vomiting.

Four patients required reoperation for more conventional surgical complications. There were three ventral hernias which required repair and one patient needed a laparotomy for division of adhesions.

Discussion

This is a small study in comparison with other international programmes. The assessment was made more difficult by the poor compliance with follow-up which resulted in 23 per cent of the group being lost to follow-up. It could be assumed that those patients absconding were treatment failures, although two had achieved a satisfactory excess weight loss (> 65 per cent) at the last attendance.

Rao[6] has reported 240 cases of gastric banding with a weight loss of 35–40 kg at the end of 12 months (mean weight 140 kg, 58 kg excess). By the third year 20 per cent started to regain weight and 10 per cent continued their weight loss. He used a silicone rubber-coated Dacron ring and has found a lower complication rate than we have. Kuzmak[7] has reported the use of an inflatable Silastic band in 45 patients with a resultant 53·5 per cent weight loss at 6 months. Lovig *et al.*[8] used a Dacron vascular prosthesis as a band and achieved a mean weight loss of 33·4 kg (27·6 ± 1·9 per cent) at 2 years in 163 patients. Serious complications occurred in ten patients and required reoperation, with one death. The band penetrated the gastric wall in three others. Our use of Dacron or Teflon bands probably induced a degree of fibrosis and may have been responsible for kinking of the stoma by adhesions to the liver. The ease with which they could be removed suggests that they were not a cause of stenosis. The results from this study suggest that the weight loss as a consequence of the operation is satisfactory, with an increasing weight loss at 2 years. Even if weight loss settles after 2 years, a loss of 70 per cent of excess weight is good. Before analysis of the results of this study it was suspected that the results would mirror those of the horizontal banded gastroplasty. Both these procedures include the fundus in the gastroplasty. Unlike the vertical gastroplasty, this then allows room for expansion. This is almost certainly the reason for the subjective increase in pouch size which has been demonstrated. An objective assessment using barium or radioisotope studies would have given more accurate assessment of pouch size[9], but our method allows patient compliance and gives at least an indication of meal size.

Technical difficulties with the gastric banding procedures focus on the tightness of the band in achieving an accurate 1·2 cm stoma diameter. When the band was too loose, gastric emptying occurred too rapidly and the patients resumed eating to satisfy hunger. Too tight a band resulted in dilatation of the proximal compartment and increased capacity with or without vomiting. Patients tended to eat to capacity, usually with poor quality high-calorie foods, and weight loss became impaired. Kuzmak[10] has used a pressure measurement of the band on

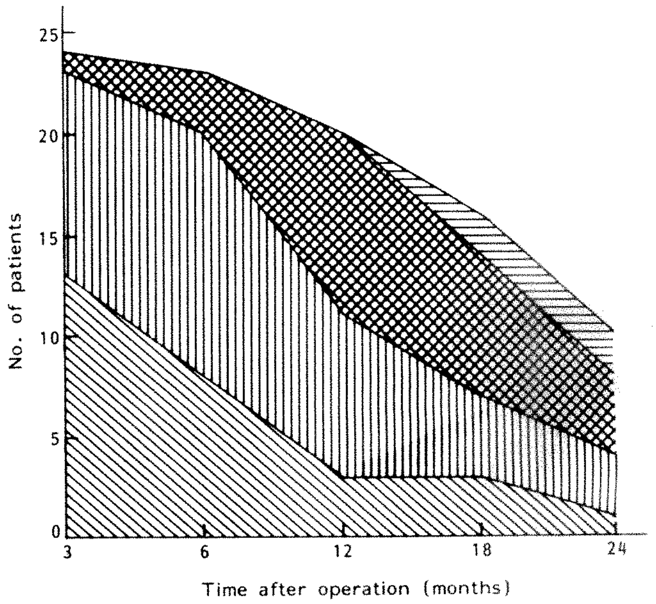

Figure 2 *Subjective assessment of pouch size. Patients estimated whether the size of meals they could eat could be served on a saucer ▧, a tea plate ▥, a dessert plate ▩, or a dinner plate ▤*

a tube passed through the stoma and by using this inflatable silicone band would appear to have best control over the stoma dimension.

If the achieved weight loss was taken in isolation the operation could be said to be successful. We have reported an extremely high rate of complications with 50 per cent of patients requiring at least one reoperation and 22 reoperations for technical complications. Four patients (13 per cent) had bandings that were too tight whereas banding was too loose in six patients (20 per cent). Perhaps use of an inflatable band would have altered these results, although adhesion formation is unlikely to allow a tight band to relax sufficiently. It is interesting to postulate the cause of intussusception in four patients, which was recurrent in two, even after two reoperations. It was probably a result of vomiting with reverse peristalsis forcing the distal compartment through the stoma. A simple revision was attempted in three patients for this condition, but conversion or removal subsequently became necessary for all three patients.

Similar technical difficulties were reported by Grandström and Backman[11] in a series of 72 patients. One-third of the patients had serious complications. Thirty-three reoperations were performed in 22 patients due to band-related problems, with two deaths. Only three revision procedures achieved a satisfactory result. Reduction in band tension gave fewer revisions but also less weight loss.

Gastric banding was introduced as an easy and cheap alternative gastroplasty. One of the reported benefits of the procedure is the ease of reversibility. Simple reversal only needed to be carried out in two of our patients but reversal plus conversion to vertical Silastic ring gastroplasty was necessary in seven further patients. This represents a 30 per cent rate of reversal and/or conversion which would appear to be an unacceptable rate of complications. We have therefore discontinued gastric banding gastroplasty as a method of treatment for morbid obesity, preferring the vertical Silastic ring gastroplasty on the basis of earlier experience in more than 100 patients using this procedure.

Single-layer bowel anastomoses have conventionally been constructed using an interrupted suture technique. A single-layer continuous technique has been avoided on the grounds that it may predispose to ischaemia of the bowel ends. We have routinely used a single-layer continuous suture technique with an absorbable suture material (polyglycolic acid) to construct all recent intraperitoneal bowel anastomoses, and we present a 3-year audit of this technique. A total of 131 patients were studied of whom 66 had undergone upper gastrointestinal resections and 65 had had colonic resections. Twenty-two patients had emergency operations. Anastomotic failure was noted in 4·5 and 6·2 per cent of patients in each group respectively. The incidence of minor wound infection was 1·5 and 7·7 per cent respectively. The overall mortality rate was 8·4 per cent. This study suggests that a single-layer continuous suture technique gives acceptably reliable results when used in gastrointestinal anastomosis.

Keywords: Colon anastomosis, polyglycolic acid

Anastomotic breakdown remains a major cause of morbidity and mortality after operations on the gastrointestinal tract. Colonic anastomoses are particularly liable to this complication. A recent large multicentre series reported an average clinical anastomotic dehiscence rate of 13 per cent with an associated three-fold increase in perioperative mortality following colonic resection[1]. Lack of suture line tension, effective bowel preparation, avoidance of ischaemia and infection, an inverting suture technique and omental overlay form the basis of a sound anastomosis[2–6]. Conventionally, an anastomosis is constructed in two layers comprising an inner continuous suture (such as catgut) and an outer interrupted seromuscular suture (such as silk). Recently, avoidance of the inner 'haemostatic' layer, on the grounds that it may compromise an already precarious blood supply, has resulted in a number of series in which the anastomoses have been constructed safely using single-layer interrupted suture techniques[5–9]. A single-layer continuous technique has always been avoided on the same premise. However, one of us (R.G.L.) has long used a simple, single-layer, continuous suture technique with an absorbable suture material (polyglycolic acid) for the construction of all intraperitoneal gastrointestinal anastomoses with apparent success; a prospective audit was therefore undertaken.

Patients and methods

All patients undergoing intraperitoneal bowel anastomoses during a 3-year period between January 1984 and February 1987 were studied. The patients were admitted under the care of the senior author (R.G.L.) who undertook all operative procedures. Data on each consecutive patient were collected during their stay in hospital and at subsequent follow-up. There was a total of 131 patients (78 men and 53 women) with a mean age of 64·3 ± 13·9 years (range 19–91 years). They were divided into two broad groups: those undergoing upper gastrointestinal anastomoses (gastric, biliary, duodenal and small bowel) and those undergoing lower gastrointestinal anastomoses (colonic). There were 66 patients in the upper gastrointestinal group (41 men and 25 women) and 65 patients in the lower gastrointestinal group (37 men and 28 women). *Tables 1* and *2* show the indications for resection and the operations involved.

There was a total of 22 emergency procedures. Five patients underwent gastric resection for bleeding peptic ulcer. Nine patients had small bowel resections for strangulation due to adhesions or hernias. Five patients underwent a right hemicolectomy, two as a result of infarction in the superior mesenteric artery territory and three secondary to obstructing carcinoma of the colon. One patient had an ileocolic bypass because of an unresectable carcinoma of the caecum. Two additional patients required left colonic resections, one for a sigmoid volvulus and the other for an obstructing carcinoma of the sigmoid colon. This last procedure was the only one 'covered' by a defunctioning colostomy.

Preoperative preparation and antibiotics

All patients having elective surgery involving a colonic anastomosis were restricted to fluids for 48 h preoperatively. Bowel preparation was achieved by sodium picosulphate, 10 mg (one sachet) at 24 h and at 18 h before operation. Gentamicin and metronidazole were used in preparation for colonic procedures and cefuroxime for upper gastrointestinal procedures; the antibiotics were given at induction of anaesthesia and continued for 24 h after the procedure. No special preoperative preparation was used for patients undergoing upper gastrointestinal anastomoses.

Operative technique (Figure 1)

Colonic anastomosis. The bowel wall was not extensively 'cleaned' at the site of proposed section. Non-crushing clamps were placed across the bowel approximately 5 cm from the line of resection taking care not to include the mesentery in the ends of the clamps. Bowel was divided between two crushing clamps. Two full thickness polyglycolic acid sutures were inserted, one at the mesenteric border and one at the antimesenteric border to approximate the bowel ends. The anastomosis was constructed with 2/0 polyglycolic acid using a continuous suture technique. The anastomosis was started at the antimesenteric border and run along using a simple 'over and over' full thickness stitch to form the posterior layer. At the mesenteric edge two Connell stitches ensured inversion of the corner and the stitch was continued 'in out, in out' to form the anterior wall and meet itself at the start of the anastomosis at the antimesenteric border. Care was taken to pull the suture tightly enough just to approximate the bowel edges and also to ensure that the bowel wall was inverted. The stay sutures were removed and the mesenteric defect was closed using 2/0 polyglycolic acid in a continuous manner. Omentum, if available, was laid over the anastomosis. All anastomoses were performed end-to-end except for the three ileocolic bypass procedures. Gross bowel disparity was corrected using an antimesenteric 'slit'. Drainage was used only for raw peritoneal surfaces.

Other anastomoses. Gastrojejunostomies and cholecystjejunostomies were constructed side-to-side in a manner similar to that used in ileocolic anastomoses. The use of clamps was kept to a minimum. Nasogastric tubes were used routinely in patients having gastric anastomoses.

Postoperative care

All patients remained on intravenous fluids with no oral intake until evidence of gastrointestinal motility was present (reduced drainage from the nasogastric tube, bowel sounds and passage of flatus). Fluids were then given orally in gradually increasing amounts and food was started 48 h later. Abdominal drains, if used, were usually removed between 48 and 72 h after the procedure. The abdominal wounds were assessed during the in-patient stay and also at the first out-patient follow-up appointment (approximately 4 weeks after discharge).

Results

Upper gastrointestinal tract

Three patients (4 per cent) had evidence of anastomotic dehiscence. Two of these three patients developed peritonitis 7 and 8 days postoperatively, one patient after a subtotal gastrectomy for an obstructing carcinoma of the stomach (confirmed radiologically) and the other after a cholecystjejunostomy for carcinoma of the pancreas (diagnosed clinically). Both of these patients died as a result of the anastomotic dehiscence. The third patient developed an intestinal fistula 8 days after an emergency resection of small bowel secondary to strangulation by adhesions.

Overall, seven patients (11 per cent) died in this group. Two deaths were considered to be secondary to anastomotic failure; the others followed myocardial infarction (one death), pulmonary embolism (one death), renal failure (one death) and bronchopneumonia (two deaths). One patient developed a pancreatic fistula following open pancreatic biopsy. The incidence of overt wound infection was 1·5 per cent.

Lower gastrointestinal tract

Four patients (6 per cent) developed evidence of intra-abdominal sepsis, which was treated conservatively. All had undergone right colonic resections, two of which were emergency operations. Two of these four patients died, one after a limited right hemicolectomy for disseminated carcinoma of the colon and the other after an extensive emergency resection for a superior mesenteric artery infarct.

Four patients in this group died (6 per cent), two patients dying secondary to anastomotic dehiscence and two others following myocardial infarction. Five patients (8 per cent) developed minor wound infections.

Discussion

The frequency of suspected anastomotic dehiscence following right colonic procedures may reflect a number of factors. Six of the 27 right colonic procedures were undertaken on an emergency basis and two of these six patients developed evidence of anastomotic failure. Both had undergone resection with primary anastomosis secondary to infarction in the superior mesenteric artery territory. Recent literature would suggest that primary anastomosis may not be appropriate in these cases despite seemingly viable bowel ends at operation. Also an assumption of the 'good' healing properties of the right colon may lead to an increased tendency to perform a primary anastomosis in spite of other relative contraindications[10].

All four patients with evidence of intra-abdominal sepsis following colonic anastomosis were treated conservatively on clinical grounds. Debas and Thomson[10] advocate an active interventional approach in the treatment of suspected anastomotic failure. Though appropriate in most situations, we feel that in some instances this view may be difficult to justify. For example, where an initial palliative procedure had been undertaken for disseminated malignancy our policy was to treat patients with intra-abdominal sepsis conservatively.

Whether the suture material used in the construction of gastrointestinal anastomoses affects outcome to a significant degree is doubtful, as demonstrated by the variety of materials used in many reported clinical series[1–9]. Ideally the suture should remain 'available' while the bowel is healing and should be completely absorbed after this process is complete. Materials that produce an excessive reaction may predispose to infection and are liable to cut out[8]. Catgut produces an intense reaction and has an unpredictable absorption rate. Silk is non-absorbable and also produces an excessive inflammatory reaction[11]. Non-absorbable synthetic materials, although inert, are foreign bodies. A number of clinical and experimental studies suggest that polyglycolic acid may be a suitable alternative[9,12–14]. However, a possible disadvantage is its braided nature which may allow infection to be harboured and which may produce mechanical damage as a result of a 'sawing' action as the suture is pulled through the tissue. We are currently assessing the use of a synthetic monofilament absorbable suture material in the construction of gastrointestinal anastomoses.

The issue of whether to have a one- or two-layer anastomosis seems as yet unresolved. Theoretically, two-layer anastomoses may predispose to ischaemia of the bowel ends[12] and reduce the lumen of the bowel[3], and there is some experimental evidence to suggest that a conventional two-layer anastomosis may not remain as two layers for very long[11]. One-layer interrupted anastomoses have been shown to be satisfactory in a number of clinical series[5–9] despite being constructed with a variety of suture techniques and suture materials.

We conclude that, in our hands, there appears to be no disadvantage in using a single-layer continuous suture technique with a slowly absorbable suture material in the construction of intraperitoneal gastrointestinal anastomoses. We suggest further that the theoretical risk of ischaemia incurred by using this technique is not substantiated in practice.

Use of a bioprosthesis to relieve tension in oesophageal anastomosis: an experimental study

Collagen-coated Vicryl® mesh was assessed as a prosthetic repair material in the oesophagus of growing piglets. In a group of six piglets (group A), a full thickness defect was created in the oesophagus without fully transecting the organ. The removed tissue was subsequently replaced with a patch of collagen-coated Vicryl mesh. Animals were killed at 4 weeks and in the five surviving piglets the prosthesis had been replaced by host scar tissue with a normal epithelial lining. Two further groups of six piglets (groups B and C) were used as controls. In group B the oesophagus was either partly transected (four animals) or completely transected (two animals) and an anastomosis was performed, whereas in group C a 2·5-cm length of oesophagus was removed so that the anastomosis was performed under tension. In group B, all six piglets survived, whereas in group C, where the anastomosis was performed under tension, only two piglets survived. Microscopic and macroscopic examination of all groups showed that the collagen-coated Vicryl prosthesis was replaced by scar tissue; moderate stenosis was observed in only one animal in group A. Collagen-coated Vicryl mesh may be used either to reinforce an anastomosis performed under tension or may find use in tubular form to bridge the gap between the two ends of the oesophagus to be joined. It is envisaged that such a material may find applications in the treatment of oesophageal atresia.

Correspondence to:
Mr R. Carachi

The outcome for infants with oesophageal atresia primarily depends on the number and importance of the associated anomalies. Irrespective of an infant's birth-weight, a 95 per cent survival rate in babies with oesophageal atresia without other major anomalies is obtained. The high incidence of other major anomalies decreases the overall survival rate of infants with oesophageal atresia to approximately 75 per cent[1]. There still remains a significant clinical problem of leaks at the site of oesophageal anastomosis, resulting in stenosis. Other recognized problems with this operation are tension, infection, foreign material, such as suture material, and ischaemia at the anastomotic site[2].

To investigate the complications at the site of anastomosis, several experimental studies have been carried out using a variety of techniques. These have involved the use of various types of oesophageal stents and transanastomotic tubes[3,4] but there remains a requirement for some method of reducing tension at the anastomosis. The use of a prosthetic patch at an anastomosis has been tested as a way of preventing tension as well as of sealing any leaks at the anastomotic site. Vicryl® (Ethicon Ltd., Edinburgh, UK) (polyglactin 910) is a copolymer of glycolic and lactic acids containing 90 and 100 per cent of each component respectively. It is a water-soluble polymer used in the manufacture of surgical sutures but, when woven into a mesh it has also found encouraging application in tissue augmentation[5]. It was envisaged that such a mesh when made leakproof with a biodegradable film such as collagen may well provide a useful prosthetic material for reinforcing an anastomosis performed in the oesophagus. Indeed, such a composite has already shown considerable potential in the repair of the urinary tract, where it has been used to augment an experimental defect created in the bladder[6], and in partial nephrectomy where it has allowed a new capsule to regenerate over the excised kidney[7]. This report describes an experimental study (in piglets) of repair of the oesophagus after transection and excision of part of the oesophageal wall.

Materials and methods

Vicryl® (polyglactin) mesh, style 9, was obtained from Ethnor, Neuilly sur Seine Cedex, France. Collagen-coated Vicryl mesh was prepared by the method of Gorham *et al.*[8]. Piglets 3–4 weeks old were premedicated with atropine, and anaesthesia was induced with halothane in a mixture of nitrous oxide and oxygen. Following intubation, spontaneous respiratory movements were abolished by hyperventilation. Each piglet was positioned for a right-sided thoracotomy and the skin, after clipping, was prepared with povidone (polyvinyl pyrrolidine iodine) and alcohol. An incision was made through skin, fascia (*Figure 1*) and muscle, down to the sixth intercostal space. The pleura was opened and, with the help of a self-retaining retractor to spread the ribs, the lung was retracted. The parietal pleura over the mediastinum was then divided and the oesophagus was

mobilized taking care to avoid the vagus nerve and segmental blood vessels. A tape sling was passed around the oesophagus once a nasogastric tube had been passed by the anaesthetist. The operative procedure was then performed as follows.

Group A (six piglets). A 2·5-cm elliptical portion of the anterior wall of the midthoracic oesophagus was excised without completely transecting the oesophagus, and the collagen-coated Vicryl mesh patch was sutured in place without tension.

Group B (six piglets). Partial (four animals) or complete (two animals) transection of the oesophagus was performed, followed by anastomosis without tension using 4/0 silk.

Group C (six piglets). The oesophagus was divided and a 2·5-cm section was removed before reanastomosis. The oesophagus was then repaired under tension using 4/0 silk sutures.

The pleura over the oesophagus was closed as a separate layer and the lungs were then gradually reinflated. Pericostal sutures of 2/0 monofilament nylon were used to approximate the ribs. The muscles were closed with a continuous Vicryl suture and the skin was closed with 2/0 Supramid® sutures (B. Braun Melsungen A.G., FRG).

An intercostal chest drain was used to aspirate air from the thorax, and was removed after complete closure of the chest wall.

Postoperative care

Pethidine (2 mg/kg) was administered by intramuscular injection before termination of anaesthesia, and subsequent analgesia was given as required. Prophylactic antibiotic cover consisted of a single dose of long-acting penicillin. The piglets were fed powdered milk *ad libitum* for 72 h postoperatively and then softened feed.

Assessment of stenosis and histology

Animals in all three groups were killed after 4 weeks, weighed, and the oesophagus was removed at post-mortem examination. After death, stenosis at the repair site in all three groups of animals was assessed by first sealing the distal end of the oesophagus by tying with a suture and filling the organ with barium sulphate before X-ray examination. The results were assessed independently by two authors (A.A. and J.R.) without knowledge of the groups. After this assessment of the stenotic area, appropriate sections were fixed in buffered formalin and processed for routine histology, using haematoxylin, phloxine and saffron (HPS trichrome) staining. The barium studies on the oesophagus at post mortem allowed a grading system for the oesophageal anastomosis. Each was graded according to whether they showed minimal stenosis (+), moderate stenosis (+ +) or severe stenosis (+ + +).

Weight gains of group A and group B piglets were compared using the Student's *t* test for unpaired samples.

Results

In group A where piglets had a collagen-coated Vicryl mesh patch, one piglet died from a leak at the oesophageal anastomosis; the remaining five piglets survived and grew as well as the control group B (*Table 1*). All six piglets in control group B survived, whereas all six piglets in group C suffered from mediastinitis. Attempts were undertaken to control this infection at the anastomotic site with broad-spectrum antibiotics, but four of the six piglets died or were destroyed on humane grounds. Two survivors developed respiratory signs at day 3, but responded to treatment. The weight gains of the piglets in group A compared with group B showed no statistically significant difference ($P = 0·8$; *Table 1*). Given that only two piglets survived in group C, there were insufficient data to assess whether the gain in weight over 4 weeks was significantly different from that seen in groups A and B. However, the values lie within the range of the weight gains of group A and B animals.

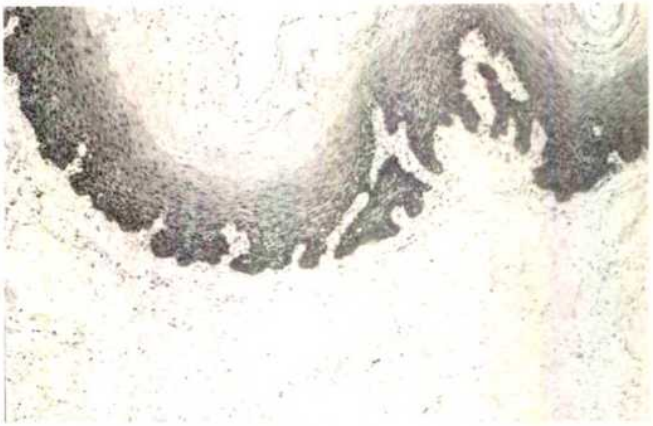

Figure 2 *Histological section of the area replaced by the collagen-coated Vicryl prosthesis. Collagen tissue has replaced the Vicryl mesh with complete epithelialization of the area*

In group A, one piglet showed evidence of moderate stenosis whereas the narrowing in the four remaining piglets was graded as minimal. In group B, five piglets showed minimal stenosis while one suffered severe stenosis. The piglet with the severe stenosis increased its weight by a factor of only 1·25 over the 4 weeks, compared with an average value of 3·17 times the original weight for the remainder of the animals in this group. In group C, the two surviving piglets showed moderate and severe stenosis respectively. Macroscopic examination of the piglets in group A revealed no sign of the prosthetic material that had been used to seal the gap 1 month previously. Histological findings of group A piglets revealed complete epithelialization of the area which had been replaced by the collagen-coated Vicryl prosthesis. It also confirmed that there was no evidence of residual Vicryl mesh, the prosthetic material having been completely replaced by new host collagen (*Figure 2*). Group B piglets revealed only a small scar with occasional granulation tissue where a suture still remained. In all four group C piglets that died, there was evidence of acute inflammation with disruption of sutures at the anastomotic site; the two surviving piglets had signs of chronic inflammation with superficial abscesses.

Discussion

The results presented in this study have shown that after repair of a full thickness defect in the oesophagus of growing piglets with a patch of collagen-coated Vicryl mesh, the prosthetic material degrades without trace and can be replaced by new host collagen with a normal epithelial lining. Furthermore, under the conditions of our experiments, the healing process was accompanied by minimal stenosis at the repair site with a normal epithelium. Of the six animals that had the collagen-coated Vicryl prosthesis, one animal died as the result of a leak from the anastomotic site. It should be emphasized that this was the first piglet on which such an operation was attempted. The remaining five piglets in this group grew as well as those in control group B in which no tension was applied to the resected oesophagus. However, the piglet with the more severe stenosis showed the least weight gain over the 4-week period.

The fact that an anastomosis performed under tension is clearly a source of problems was demonstrated by the difference in the two control groups. In group C, where a 2·5-cm length of oesophagus was removed before the anastomosis, only two animals survived the 4-week period and, even then, clear evidence of mediastinitis could be demonstrated in these animals at post mortem. In addition, moderate and severe stenosis at the site of the anastomoses could be seen in these two piglets both by visual inspection and by X-ray examination. In contrast to group C, however, five of six animals in group A survived following anastomosis in which no tension was applied to the anastomosis site by removing a section of oesophagus. These showed only minimal stenosis. Furthermore, unlike all the group C animals in which clear evidence of mediastinitis could be demonstrated histologically, together with disruption of sutures and inflammation at the anastomotic site, group A animals showed little evidence of ulceration.

Collagen-coated Vicryl mesh has already been applied to the protection of oesophageal anastomoses in 27 adult patients[9] with encouraging results, including a decrease in the rate of postoperative fistula formation at the operative site. It should be emphasized, however, that the material was wrapped around the anastomotic site and was not tested in 'growing patients' as would pertain in oesohageal atresia; nor was an attempt made to replace a full thickness tissue defect. Another study attempted the replacement of 4 cm of cervical oesophagus with a tube of Vicryl mesh[10]. However, severe problems were encountered with stenosis, and dehiscence at the operative site was a considerable problem, presumably because Vicryl mesh is not leakproof unless given a collagen coating.

Our own results have demonstrated that the collagen-coated Vicryl mesh degrades without trace at 4 weeks and can be used in the repair of full thickness defects where it is replaced by host scar tissue with a normal epithelium. The results are sufficiently encouraging to indicate that such material may be useful in the reconstruction of a section of oesophagus or as a means of reducing anastomotic tension, a factor clearly contributing to operative failure at oesophageal anastomoses.

Acknowledgements

We would like to thank Mrs Sylvia McCulloch for her secretarial assistance, Mr D. G. Young for his support in this study, and Miss J. McKenell, the veterinary nurse who looked after the animals so well.

This article reviews the clinical manifestations of Yersinia *bacteria emphasizing their recent rise in incidence and describing how* Yersinia *infection presents to the general surgeon. Geographical variations, patterns of disease, pathogenicity and the problems in diagnosis and management are discussed. This common but often unrecognized infection is usually self-limiting but the very young, the very old and the immunocompromised are at greater risk and prompt treatment is required to save lives.*

Keywords: *Yersinia enterocolitica, Y pseudotuberculosis,* gastroenteritis, abdominal pain, appendicitis, arthritis

Although first described by Schleifstein and Coleman in 1939[1] infection with bacteria from the *Yersinia* group was rarely diagnosed before the 1960s. At that stage most diagnoses were made in patients with self-limiting colitis or mesenteric adenitis[2,3] Since then it has become apparent that *Yersinia* species produce a variety of diseases with severity ranging from self-limiting to life-threatening, especially in the very young, the very old or the immunocompromised. Since 1970, when the genus was formally united[4], the number of cases diagnosed has risen exponentially[5,6]. Whether this increase reflects an increased awareness of the organism, a rise in the true incidence of disease or an improved diagnostic capability is uncertain.

By far the majority of illnesses are gastrointestinal in nature, usually with associated abdominal pain or diarrhoea, hence the frequency with which they present (often unrecognized) to the general surgeon. As well as this, yersiniae are capable of producing suppurative infections in many organs, various inflammatory reactions such as arthritis and thyroiditis, and occasionally overwhelming infections such as septicaemia and meningitis.

Characteristics of Yersinia bacteria

Yersinia species include *Y. pestis* (*Pasteurella pestis*), *Y. pseudotuberculosis* (*P. pseudotuberculosis*), *Y. enterocolitica* (*Pasteurella X*), *Y. frederiksenii, Y intermedia* and *Y. kristensenii* and are all members of the family *Enterobacteriaceae*[7]. The pathogenic serotypes of *Y. enterocolitica* include 0 3 (worldwide), 0:5, 0:6, 0:7, 0:8 (North America), and 0.9 (Europe)[5]. *Y. pseudotuberculosis* has at least six pathogenic serotypes (I–VI) but the relative pathogenicity of each type has not been fully investigated[8]. *Y. pestis* is the cause of bubonic plague and the remaining *Yersinia* species (*Y. frederiksenii, Y intermedia* and *Y. kristensenii*) have only been described in occasional reports

Yersiniae are Gram-negative rods, and their biochemical profiles are included in the commercial multitest systems and in the computerized identification schema that are used in most laboratories. The bacteria grow on a variety of culture media but colonies are small and slow growing compared with other enterobacteria. They are characteristically pale lactose non-fermenters whereas colonies of *Escherichia coli* are pink lactose fermenters. *Yersinia* species have a preference for cold environments. Their optimal culture temperature is 22°C[9] and it is at this temperature that they are motile[10], they are non-motile at 37°C They can continue to grow at or below 4°C. As there may be a natural reservoir of organisms in meat, particularly pork[11,12] and vegetable products[13], the normal processing and refrigeration of these foodstuffs may allow continued growth of these organisms[14]. Their ability to grow in the cold may also explain the significant seasonal variation of clinical infections which are maximal in the cooler months of the autumn and winter[15–17].

Most infections are sporadic or endemic. There have been a few well-documented epidemics of yersiniosis from village drinking water[18,19], from infected milk[20] and from milk chocolate[21]. The mode of spread in the majority of cases is oral ingestion of contaminated food[22]. Although *Y. enterocolitica* has been found to infect a wide variety of animals, notably chinchillas, hares, sheep, horses and cattle, most of the reported infections in these animals have been with serotypes that are not found in the human disease However, pigs (and less frequently cats and dogs) have been regarded as the main reservoir for human infections[23]. In the case of *Y. pseudotuberculosis*, zoonosis has also been reported[24]. For both species occasional outbreaks of familial[25–27], hospital[28,29], transplacental[30] and blood transfusion[31] infections have occurred.

Geographical variations

The geographical variation in *Yersinia* infections is of particular interest Yersiniosis has been reported from most parts of the world but there is a marked variation in both the frequency and the serotype pattern of the disease in different countries Although first described in Britain in 1960, relatively few cases are diagnosed in Britain and Ireland today However, the incidence is rising rapidly[6] The northern European countries of Belgium, the Netherlands and Scandinavia have recognized *Y. enterocolitica* as an important bacterial cause of gastroenteritis for many years[32,33] but, despite its frequency in these northern European countries, it is a relatively rare disease in neighbouring France.

The USA[34], Canada[35], Japan[36] and Australia[37,38] have all reported large numbers of cases in geographical pockets and the range of pathogenic serotypes differs from the European experience. Infection with *Yersinia* species has been regularly reported from eastern Europe and Russia, usually from contamination by yersiniae of foodstuffs and drinking water[39]. The cause of such marked variation in geographical pockets is something of an enigma. It is not due to an inability to grow

0007–1323/89/050499–06$3 00 © 1989 Butterworth & Co (Publishers) Ltd

the organism, or to a lack of surveys to search for it. Socioeconomic factors, dietary customs, farming and food storage methods have been implicated but, currently, there is no satisfactory explanation to account for the geographical variations of *Yersinia* infections.

Patterns of disease

Gastrointestinal

When specifically sought using selective techniques, *Y. enterocolitica* is a common isolate from stool cultures of patients with gastroenteritis. In northern Europe *Y. enterocolitica* is ranked immediately below *Salmonella* in frequency of isolation from cases of gastroenteritis and is of the same order of frequency as *Shigella*, *Campylobacter* and *E coli*[5]. *Yersinia* gastroenteritis is usually acute in onset, mild to moderate in severity and associated with malaise, pyrexia, abdominal pain and erythema nodosum[32]. Other extraintestinal symptoms may also present during the acute attack. The condition lasts from a few days to a few weeks but in most cases is self-limiting and resolves without treatment[40], although excretion of the organisms in the stool may continue for several weeks Enteritis with *Y. enterocolitica* may however progress to early fulmination, with toxic dilatation[41] and perforation of the ileum[42] or colon[43], and these cases will require immediate surgical intervention. Unfortunately there is no way of predicting such progression and diagnosis rests on clinical observation.

Yersinia is a common cause of acute terminal ileitis[44–46], diagnosed at laparotomy, and this is particularly associated with *Y. enterocolitica*. Despite occasional reports[47], no definite relationship has been identified between *Yersinia* and either Crohn's disease[48,49] or ulcerative colitis, but there are many cases of chronic non-specific inflammatory bowel disease that may be the end result of enterocolitis due to *Y enterocolitica*[50,51].

The predilection of *Yersinia* infections to the right iliac fossa is not confined to the terminal ileum. Both *Y. pseudotuberculosis* and *Y. enterocolitica* are frequent causes of mesenteric adenitis[2,52,53]. *Y enterocolitica* 0·9[33] and *Y pseudotuberculosis* appear to cause more abdominal pain syndromes than bowel disturbances and these include a spectrum of right iliac fossa pains that range from the non-specific to mesenteric adenitis (predominantly *Y. pseudotuberculosis* serotype I), acute terminal ileitis and actual appendicitis (predominantly *Y. pseudotuberculosis* serotype IV)[54].

The association of *Yersinia* infection with appendicitis was first suggested by Winblad *et al* in 1966[55], when they demonstrated a 6 per cent prevalence of antibodies to *Y enterocolitica*. At that stage the only serotype of *Y. pseudotuberculosis* that was considered pathogenic was serotype I and few workers considered it in their investigations Since then, Jepsen *et al.*[56] and others [57–66] have cultured *Y. enterocolitica* from appendices and have demonstrated rises in related specific antibodies. In one recent study *Yersinia* infection was present in 31 per cent of acute appendicitis cases (27 per cent *Y. pseudotuberculosis* and 4 per cent *Y. enterocolitica*) and the predominant serotype was *Y. pseudotuberculosis* IV[54].

The relationship of *Yersinia* to acute appendicitis deserves further study. It may be that suppurative appendicitis is a secondary infection of an appendix that is primarily infected with *Yersinia* and that those cases that are labelled right iliac fossa syndrome or non-specific abdominal pain have *Yersinia* infection in the lymphoid tissue of the appendix, terminal ileum or mesenteric nodes, or a combination of these, with spontaneous resolution. This hypothesis provides a useful working guide to the pattern of *Yersinia* infections in acute abdominal pain syndromes. In the majority of cases the clinical outcome of *Yersinia* appendicitis, mesenteric adenitis or acute terminal ileitis is no different from any of these conditions without proven yersiniosis[54,66] However, chronic colitis and abdominal pain after appendicectomy have been reported[41,54] and these sequelae are easily treated with appropriate antibiotics.

Other gastrointestinal infections have been reported less frequently Small bowel gangrene[67], intussusception[68,69], primary peritonitis[70–72], hepatic abscesses[73–75] and pancreatitis[76] have been occasionally reported and these more serious conditions are often found in debilitated or immunocompromised patients

Children

Yersinia as a cause of non-specific abdominal pain and diarrhoea in children has received considerable attention[21,77–85] The pattern of disease is age dependent and by far the commonest serotype identified has been *Y. enterocolitica* 0:3 (*Table 1*) In children under the age of 5 years an acute self-limiting diarrhoeal illness occurs, while in those over the age of 5 years apparent pseudoappendicitis predominates[61]. In children with non-specific abdominal pains or enteritis there is often an associated pharyngitis, and throat swabs from such children have demonstrated *Y. enterocolitica* as the sole infecting organism[21] *Yersinia* has also been cultured from uncomplicated cases of pharyngitis[86].

Suppurative infections

Yersinia as a cause of acute suppuration is relatively rare. Cultures from pus from pyomyositis[87], lung abscesses[88,89], occasional pneumoniae[90], cerebellar abscesses[5], lymphadenitis[32] and osteomyelitis[91,92] have yielded growths of *Yersinia* species, both *Y. enterocolitica* and *Y. pseudotuberculosis.*

Generalized fulminating infections

Many cases of *Yersinia* septicaemia have been reported and 50 per cent of these were fatal[24,63,79,92–95]. In general, *Yersinia* septicaemia has been reported in the already debilitated, or in those with thalassaemia major, haemochromatosis, or other form of iron overload[96], usually receiving treatment with desferrioxamine

Immunologically mediated disease

Yersinia infections have been related to the development of a number of non-suppurative inflammatory conditions The most frequent of these is acute arthritis, and in Scandinavia *Yersinia* is regarded as the commonest cause of acute non-rheumatoid joint inflammation[97–100]. The arthritis is mono- or polyarticular, commences after a latent period of 1–3 weeks and produces joint swellings which on aspiration show the presence of a moderate lymphocytosis Extension to other arthritic syndromes includes ankylosing spondylitis and Reiter's syndrome, and those with the histocompatibility antigens HLA B27 are known to be more susceptible[101]. Erythema nodosum[32,98] and tenosynovitis[32] are frequently found in *Yersinia* infections, either on their own or in combination with an antecedent history of acute gastroenteritis and fever or with a concomitant acute arthritis.

An association of thyroid inflammatory disorders[102] and *Yersinia* antibodies has been demonstrated but in some cases this has been correlated with the production of thyroid autoantibodies[103] and the relationship may be due to the presence of *Yersinia* infection at some remote site, precipitating the development of autoantibodies owing to a shared antigenic

Table 1 *Frequency of bacterial isolation from children with gastroenteritis in major European and North American centres*

	Sweden (Uhnoo *et al.*[84])	Canada (Marks *et al* [82])
Yersinia enterocolitica	5·6	2·8
Escherichia coli	4·2	—
Campylobacter	2·8	—
Salmonella	2·8	4·4
Shigella	0·7	1·1

The values are percentages

structure. Whether such a relationship pertains to the development of a *Yersinia* IgA glomerulonephritis[104–106] or whether this rare condition is due to the deposition of *Yersinia*–antibody complexes in the renal basement membrane is not yet known[107]. A similar association has been made between *Yersinia* infection and myocarditis and pericarditis[32].

Diagnosis

The diagnosis of *Yersinia* infection rests, ideally, on the combined culture of the organism and demonstration of a rise and fall of specific serum antibodies correlated with the clinical course of the disease[108]. In many cases the diagnosis cannot be made by culture owing to the inaccessibility of an infected site. Even in cases of gastrointestinal disease, where faeces provide an available culture substrate, the presence of *Yersinia* is not always correlated with specific disease.

The presence of *Yersinia* species in the stool could be due to the passage of transient non-pathogenic bacteria while the absence of *Yersinia* from the faeces does not exclude the presence of infection in the mesenteric nodes, or another site, from which no excretion of the organisms is occurring. Isolation of *Yersinia* species from the mixed growth obtained from faecal culture is limited by the small size and lack of distinguishing features of the colonies unless specific selective media or other techniques are employed By using prolonged cold enrichment and a bench microscope the pick-up rate can be greatly increased[109]. Thus in many cases the diagnosis rests on the demonstration of a rise of specific antibody to a single pathogenic *Yersinia* serotype[108].

The need for serial sampling has recently been stressed and this introduces a delay of 10 days or more in the diagnostic process[54]. The problem of detection is made more difficult by the need to test serum against every known *Yersinia* pathogen, amounting to more than ten serotypes in many areas.

A variety of methods for antibody detection have been described. One of the most accurate is enzyme-linked immunosorbent assay[110], but direct tube agglutination (with adequate dilutions to avoid the prozone phenomenon)[108] and the differential detection of IgA and IgM antibodies by specific techniques are practical alternatives[111]. The specificity of these investigations is extremely high with a few notable exceptions. Antibodies to *Y enterocolitica* 0.9 cross-react with *Brucella* species[112] and this problem is difficult to resolve. Unless there is an endemic incidence of brucellosis, however, the problem is rarely of practical importance. Cross-reactivity of *Y. pseudotuberculosis* II with *Salmonella* of group B and *Y. pseudotuberculosis* IV with *Salmonella* of group D, however, is overcome by absorbing the serum with the cross-reacting antigens before measuring the agglutinating titre[34,54]

A fourfold rise in antibody titre or a significantly elevated titre with subsequent fall is compatible with the presence of invasive infection. In our own laboratory we recognize an antibody titre of 1/160 for *Y. enterocolitica* and 1/320 for *Y. pseudotuberculosis* as significantly elevated on direct tube agglutination, values similar to those used at the *Yersinia* reference laboratory in Leicester, UK[113]. The rise in serum antibody occurs after the first week of illness and remains elevated for a period of 1–3 months, depending on the course of the disease, before declining to normal levels[2,53,55,114].

Transient elevations of *Yersinia* antibodies occur in less than 2 per cent of the normal healthy population and, depending on the frequency of endemic infection, low titres may be present in normal subjects[54]. Cultures from appendices, mesenteric nodes and other resected material have yielded *Yersinia* species but the yield is low relative to the frequency of serum antibody rise[56]

Pathogenicity

The pathogenicity of *Yersinia* species is very variable and this creates difficulty in correlating the presence of these organisms with actual disease. A most significant finding was that of plasmid-mediated tissue invasiveness discovered by Zink *et al.* in 1980[115]. *Y. enterocolitica* was the first bacterium in which this plasmid effect was demonstrated and this phenomenon has since been shown in *Salmonella*, *Shigella* and *E coli*. The plasmid causes a number of changes in surface proteins and induces resistance to the bactericidal effect of human serum[116,117] and to the immune mechanisms of the intestine in rat models[118].

Animal models show that the initial events in the pathogenesis of *Y. enterocolitica* infection are entry of the organisms into cells, followed by intracytoplasmic replication[119]. It is not yet known whether the production of enterotoxin by yersiniae is relevant to the development of enteric disease but it has been shown that *Y. enterocolitica* will produce toxins only when the bacteria are grown in cell lines and not on nutrient media[120]. Thus if *Yersinia* toxin does play a role in enteritis it must either be ingested or be produced only after invasive infection rather than during intraluminal replication.

Another major factor in the pathogenicity of *Yersinia* species is their predilection for iron[121]. Unlike most other aerobic bacteria, yersiniae produce no detectable iron-binding compounds, or siderophores, and must utilize iron bound by other bacteria. Hence it can flourish in the intestine but in the tissues it must compete with host iron-binding proteins for available iron. Whether this explains its predominance in the area of the terminal ileum where iron is absorbed is purely conjectural. However, in patients with conditions such as iron overload, thalassaemia[122] and haemochromatosis, particularly when treated with desferrioxamine[24], the organism has a ready supply of iron and can thrive (desferrioxamine is a bacterial iron-binding protein or siderophore). Even patients with accidental iron overdose who have been treated with desferrioxamine have died from *Y. enterocolitica* septicaemia[123].

Alcoholism, cirrhotic liver disease and diabetes mellitus all increase the susceptibility to and severity of *Yersinia* infections[124,125].

Pathological features

Macroscopically, *Yersinia* produces few distinguishing features. In the gastrointestinal tract, inflammation produces diffusely swollen, erythematous and friable mucosa[46,51]. The inflamed mucosa of the colon may be covered by a pseudomembrane and the serosal surfaces may be covered by a serosanguinous, fibrinous exudate so that loops of bowel become focally adherent. Ulcers occur and are small, shallow and oval, similar in appearance to aphthoid ulcerations seen in Crohn's disease[43,48,126,127]. Microscopic examination shows chronic non-specific inflammation with infiltration of mostly mononuclear cells and lymphocytes and few polymorphonuclear cells[128] Plasma cells, giant cells or sarcoid-like granulomas are rarely found in colonic disease but sections of infected mesenteric nodes and lymphoid tissue in appendices and the Peyer's patches of terminal ileum have shown granulomas, microabscesses and necrosis of the lymphoid follicles[128,129].

The degree of local tissue destruction in these infections is very variable. Correlation from animal experimental work is difficult as strains that are pathogenic to humans have variable pathogenicity in mice, gerbils, guinea pigs and rabbits[130–134].

Strains of *Y. pseudotuberculosis* that cause mild illness in humans have produced an overwhelming mesenteric adenitis in monkeys that proves rapidly fatal[135–137]

Management

Knowledge of the presence of *Yersinia* infection influences the management of the patient in a number of ways. In the majority of intestinal conditions, no specific treatment is required other than general supportive measures. Most cases of abdominal pain or diarrhoea are self-limiting and the diagnosis is often made retrospectively. Prolonged illness is an indication for specific therapy. Early treatment of yersinial arthritis is recommended as spontaneous resolution may take several weeks. Whether antibiotic therapy prevents the development of ankylosing spondylitis or related complications is uncertain Patients with acute or chronic colitis or chronic abdominal pain show rapid improvement with relevant antibiotic therapy[54].

Suppurative forms should be treated by traditional surgical drainage and institution of antibiotics *Yersinia* species are sensitive to tetracyclines, aminoglycosides, co-trimoxazole and chloramphenicol[34]. Most are resistant to penicillins and cephalosporins as yersiniae produce a number of β-lactamases[138]. *In vitro* sensitivity to nitrofurantoin is often demonstrable but nitrofurantoin lacks *in vivo* activity. The usual antibiotics of choice are tetracycline, co-trimoxazole and chloramphenicol, depending on the severity of the illness and the age of the patient.

In cases of right iliac fossa pain the use of antibiotics cannot replace the need for surgery of suspected appendicitis. Even if a rapid serological diagnosis could be made it would not obviate the potential progression to suppurative appendicitis and treatment must be guided by the clinical signs. However, in patients with protracted non-specific abdominal pain a serological diagnosis of *Yersinia* infection indicates the need for antibiotic therapy which is usually effective[54] In most patients with *Yersinia*-related appendicitis no change in therapeutic policy is required. The exceptions are those rare cases of patients with persistent postoperative right iliac fossa pain where tetracycline has proved useful[32].

Antibiotic treatment of the inflammatory disorders of thyroiditis and glomerulonephritis is unlikely to be helpful but Reiter's syndrome, erythema nodosum and tenosynovitis have improved with tetracycline therapy.

Identifying *Yersinia* species as the causative organism of disease in the community or hospital environment raises questions about the source of infection. *Yersinia* infections in hospital patients with diarrhoea or an open infected wound are a potential source of nosocomial infection Despite the fact that many foodstuffs and drinking sources have been identified as a source of infection, the origin of most cases of yersiniosis remains obscure Further work in this direction might not only identify the source but could provide the means to reducing the incidence of such common illnesses as appendicitis, gastroenteritis and acute arthritis

Conclusions

Acute infections, ranging from self-limiting gastroenteritis to severe gangrenous colitis with perforation and/or septicaemia, are associated with infection by *Y. enterocolitica* and *Y. pseudotuberculosis* It is now clear that the infection is zoonotic and human isolates are usually pathogenic. *Y. enterocolitica*, which is now the most common *Yersinia* type isolated, shows a marked geographical variation While *Y enterocolitica* 0 3 is found worldwide, 0 9 is prevalent in northern Europe, and 0:8 in North America In addition, it is clear that many human and environmental isolates are of low pathogenicity while some serotypes are highly virulent

In surgical practice, *Yersinia* infections are usually associated with the gastrointestinal tract *Y. pseudotuberculosis* is the most frequent bacterial cause of acute mesenteric lymphadenitis and is associated with acute terminal ileitis or acute appendicitis. In contrast, invasive and non-invasive enterotoxin producing strains of *Y enterocolitica* are a frequent cause of self-limiting gastroenteritis Invasive strains are the most common recognized bacterial cause of acute terminal ileitis. They also cause non-specific abdominal pain or 'pseudoappendicitis' and, occasionally, acute colitis or acute appendicitis. *Y. enterocolitica* 0.8 which has been isolated only in the North American continent causes a severe gangrenous enterocolitis which may be fatal. Except in rare circumstances, surgeons will not encounter this infection causing clinical problems for two reasons. The first is the variability in clinical presentation and geographical variation in incidence and prevalence of the different *Yersinia* serotypes. The second and more important reason is that *Yersinia* infections are usually self-limiting and in only a minority of cases does the infection become life-threatening. Microbiological reference laboratories provide specialized investigations to assist in the diagnosis of difficult cases but discretion should be exercised in their use. However, surgeons should be aware of the epidemiology and spectrum of organisms that infect their environment so that they may be able to recognize those patients that require accurate diagnosis and specific therapy.

Leucine kinetics in surgical patients I: a study of the effect of surgical 'stress'

R. A. Harrison, M. R. Lewin, D. Halliday* and the late C. G. Clark

*Department of Surgery, University College London and *Nutrition Research Group, MRC Clinical Research Centre, Watford Road, Harrow, UK*

Correspondence to:
Mr R A. Harrison, Department of Surgery, Edgware General Hospital, Edgware, Middlesex
HA8 0AD, UK

At present there is no consensus about the effect of surgical and accidental trauma on protein metabolism. Leucine kinetics, an index of protein turnover, have been studied in ten patients before intra-abdominal surgery and on either the third (n=5) *or seventh* (n=5) *postoperative day. Only small changes in leucine kinetics were noted in the early postoperative study but, by the seventh day, there was evidence of increased synthesis as part of an overall elevation of turnover rates. It is suggested that the previously expressed opinion that protein synthesis is reduced after surgery must be re-examined.*

Keywords: Leucine kinetics, protein turnover, surgery, surgical stress

Protein metabolism is a dynamic process. Although this concept was first suggested by Magendie in 1823[1], it was not established scientifically until the work of Schoenheimer was published posthumously 40 years ago[2]. In the last decade, isotope tracer methods which are able to quantify the dynamic aspects of protein turnover have been used to examine the nature of the disturbed nitrogen metabolism observed after surgical and accidental trauma. Such studies, it has been suggested[3], could form the basis of a greater understanding of the pathophysiology of nitrogen loss and therefore contribute to the development of more rational methods to modify the nitrogen loss in traumatized patients. Furthermore, these methods might also be used to monitor the effects of such therapy biochemically.

Since isotope tracer studies were introduced to this area of surgical research there have been several independent studies. Opinion is equally divided between those authors who report increased protein synthesis after trauma[4–7], and those who observed suppression of activity[8–11]. One report[12] failed to show any change. Several authors have commented on this dichotomy and are agreed that nutritional factors probably account for much of the apparent disparity[6,12]. Furthermore, these data have been obtained using six distinctly different methodologies and variable timing of the postoperative study.

In an attempt to clarify these apparently contradictory results, a study using a well-established isotope tracer method has been carried out in ten patients before and after intra-abdominal surgery.

Patients and methods

Patients, before resectional surgery for colonic neoplasms, were randomly allocated to one of two groups. Patients in group 1 ($n=5$) had an infusion study preoperatively and a second 7 days after surgery. Patients in group 2 ($n=5$) also had a preoperative measurement but the postoperative infusion study was carried out 3 days after surgery. Anthropometric details of the two study groups and the operative procedure carried out are given in *Table 1*. Lean body mass (LBM) was calculated from the patient's height and weight[13]. Postoperatively no patients received any nitrogen intake and fluid balance was maintained with normal saline and 5 per cent dextrose (1675 kJ day^{-1}). Leucine kinetics were measured after a 12-h fast using a primed, constant infusion of L-[1-^{13}C]leucine[14]. The [^{13}C]leucine enrichment was 99 per cent (KOR Isotopes, Cambridge, Massachusetts, USA). At the start of each infusion a bolus injection of L-[1-^{13}C]leucine (1 mg kg^{-1}) and labelled bicarbonate (0·16 mg kg^{-1}) was given to prime the relevant pools. An infusion of L-[1-^{13}C]leucine (1 mg kg^{-1} h^{-1}) was continued throughout the study, which lasted for 6 h. Samples of plasma and expired air were collected every 30 min once a plateau was established. Two measurements of carbon dioxide production rate were made using a timed Douglas bag collection method. The ^{13}C-enrichment in plasma α-ketoisocaproate was measured using a gas chromatograph mass spectrometer, using the derivatization procedure of Rocchiccioli *et al*[15]. α-Ketoisocaproate measurements were made rather than leucine as it has been suggested that they reflect more accurately the enrichment close to the site of protein synthesis[16]. The ^{13}C-enrichment in expired air was measured using an isotope ratio mass spectrometer. This was used to calculate the four parameters of leucine turnover (flux, leucine oxidation, leucine release 'from' and incorporation 'into' protein) using the formulae proposed by Matthews *et al*[17]. These are based on a simple model of protein metabolism that contains a single pool of protein in equilibrium with a second single pool of amino acids (*Figure 1*). In a steady state it is assumed that movements in and out of the amino acid pool, known as flux (Q), are equal. Amino acids enter the pool from dietary sources (I) and as a result of protein breakdown (B); they leave the pool when incorporated into protein (S) or when oxidized (C). Thus in a steady state.

$$Q=I+B=S+C$$

Results were expressed as micromoles of leucine per kilogram LBM per hour. This may be converted to grams of protein per kilogram per day using the conversion factor 590/24, but this conversion is valid only if it is accepted that leucine is a reliable tracer for whole body protein and that leucine represents 7·8 per cent of mixed body protein[17].

The results were expressed as medians and ranges and analysed by non-parametric statistics using the Mann-Whitney U test. Confidence intervals have been advocated for use in reporting results[18], and for groups of five analysed non-parametrically the range represents the 94 per cent confidence interval.

Results

The parameters of leucine turnover, flux (Q), synthesis (S) and breakdown (B) were well matched in the two groups preoperatively. Full details of the pre- and postoperative kinetic data are given in *Table 2* (group 1) and *Table 3* (group 2). It should be noted that oxidation of leucine (C) was in fact significantly higher in group 2 preoperatively ($P<0·05$). The reason for this was unclear. There was an increase in flux postoperatively when measured on the seventh day (group 1). A similar trend was evident in the early postoperative study (group 2); however, the confidence interval straddles zero. In a fasted patient, flux (Q) is equal to breakdown (B) as there is no contribution from exogenous sources of leucine. Considering the data that relate to synthesis (S), in group 1 there was a wide range but the results exclude a significant reduction in synthesis postoperatively. A similar result was obtained in group 2. However, the range is smaller and the results are grouped around zero, suggesting no clinically significant change in synthesis. The efficiency of nitrogen reutilization was measured by examination of oxidation as a percentage of flux (C/Q per cent). The higher the value of this index, the lower the efficiency. On first inspection the data suggest a more

marked deterioration in nitrogen economy 1 week after surgery (group 1) than was observed on the third postoperative day (group 2). However, it should be noted that there was an unexplained higher value for oxidation in the patients in group 2 before surgery and this was reflected in the preoperative value of oxidation as a percentage of flux. In group 2 the rate of nitrogen reutilization did not change but remained at the lower level observed in this group before surgery.

Discussion

Studies of whole body protein turnover cannot be used to address the question of the clinical significance of nitrogen loss, although they may describe, in terms of net synthesis and breakdown, the basis of negative nitrogen balance The studies are descriptive and if such methods are to be used as a basis for future investigations the ambiguity that currently exists in the literature must be examined and where possible explained. Two of the early studies are commonly quoted as evidence for postoperative suppression of protein synthesis The study reported by O'Keefe *et al*[9] looked at four patients with a mix of surgical pathologies before and after surgery; however, the patients were fed preoperatively and fasted after surgery. Attention has been drawn to this flaw in the experimental design[5,6,8] The effect of nutrient withdrawal has been investigated in several studies and opinion is unanimous that fasting causes a reduction in protein synthesis. The reductions reported are between 30 and 40 per cent in burns patients[19], preoperative patients[6] and in volunteers[20,21] Thus the 12 per cent fall in protein synthesis postoperatively reported by O'Keefe *et al.*[9] is less than would be predicted as a result of nutrient withdrawal alone. The second study was the subject of two publications[10,22] There is no evidence about how many individual patient studies were common to both reports; however, the conclusions regarding flux are the same. There was no change in this parameter postoperatively in either report The conclusions concerning synthesis were, however, different· the initial report[22] showed no change after surgery and the second[10] showed a reduction This change may be attributable to differences in the method of measuring mean nitrogen loss for the purpose of the calculation In another study[11] children were studied before and after reconstructive

surgery The postoperative nitrogen intake was 22 per cent lower than the preoperative value and though statistical analysis shows this to be 'not significant' that does not ensure that there was no effect on the level of protein synthesis.

Nutritional intake was controlled by the administration of total parenteral nutrition in a later study[12] which reported that the parameters of protein turnover were not altered by surgery. Even this protocol was not ideal as there was a break in the administration of total parenteral nutrition over the surgical period and it was only restarted 2 h before the second study.

Two studies have been carried out after accidental trauma: one in burns patients[4] and the other following major skeletal injury[5]. In both studies an increase in protein synthesis was noted along with a rise in breakdown leading to a net nitrogen loss. Of three investigations carried out in the perioperative period, two[6,7] reported a general increase in turnover, including synthesis, in fed patients. In the other study[8] examining the effect of a synthetic growth hormone, a reduction in synthesis was noted as part of an overall reduction in turnover in the control group. This study used a 24-h primed constant infusion of [^{15}N]glycine and subjects were fasted only for a period of 6 h before the start of the infusion. There is evidence to suggest that patients do not achieve a basal state in such circumstances and that the data obtained using a ^{15}N-methodology will reflect the previous fed state[21]. When dietary intake was fully controlled by intravenous feeding and turnover was measured using a very similar primed constant infusion methodology, turnover (including synthesis) was increased postoperatively[7].

From this review it is possible to conclude that several reports suggesting a reduction in synthesis postoperatively can no longer be accepted in support of that hypothesis without significant reservations. The evidence is that unless there is absolute comparability of nutritional intake, the effects of surgery may be masked by greater changes resulting from nutritional factors.

The present study has approached this problem by carrying out both pre- and postoperative studies in the fasted state; even this protocol is a compromise and does not give absolute comparability The preoperative study followed an overnight fast, while the postoperative measurements were made after a further 3 or 7 days during which there was no nitrogen intake and only 1675 kJ day^{-1} of energy supplied. The data available suggest that this is an acceptable protocol Using a leucine-based method it has been demonstrated that synthesis falls by 40 per cent within 12 h of starting a fast, and after 3 weeks on a low calorie, no nitrogen regimen subjects still had a synthesis rate 40 per cent lower than normal[23]. The results from the present study support the hypothesis that there is no reduction in synthesis after surgery. Indeed there is a suggestion that it may rise as part of an overall increase in turnover

This observation is very much in keeping with the traditional view of the metabolic response to stress. When the negative effects of nutrient withdrawal on protein synthesis are excluded then the predominant effect of stress would appear to be anabolic. This response is characterized by the production of the acute phase proteins, immunoglobulins and the proteins required for tissue repair. Many of these proteins have very short half-lives and the increased plasma levels are associated with high rates of protein turnover. In the absence of an external source of nitrogen, as nitrogen turnover is less than 100 per cent efficient, this increase in protein synthesis must be matched by an even greater level of nitrogen release. These changes result in the observed negative nitrogen balance. It can be argued that such an increase in turnover, despite its adverse effect on the nitrogen economy, is advantageous to the organism as it ensures that there can be a rapid response to the variable demands for protein synthesis that characterize the period after injury.

The present study for the first time examined the question of time-related changes in protein kinetics after surgery. The results suggest that there is a lesser effect in the early postoperative period, when flux and synthesis remain close to preoperative values. By 1 week after surgery the results, while showing a wide range, suggest that the overall effect is one of increased turnover with both synthesis and breakdown increased. If it is accepted that the two postoperative studies were carried out under comparable nutritional conditions it is possible to speculate about other factors that might account for the biphasic postoperative response One possibility is the level of mobility, low in the early postoperative period and returning towards normal at 1 week. Immobility is a potent suppressor of protein synthesis[24], although no studies of bed rest and rehabilitation have been reported. The results of the present study suggest that time after surgery as well as nutritional intake should be standardized in any future studies.

It may be concluded both from the study reported here and from the literature review that in the case of accidental trauma the data suggest that protein turnover, including synthesis, is increased A similar pattern is suggested by some of the perioperative reports, including the present study. In each case where it is reported that synthesis is reduced postoperatively, there would appear to be an unacceptable level of nutritional control in the experimental design considering the known characteristics of the tracer methodology.

Appendix

Some preliminary isotope data from this study were included in a previous publication[25]. Six patients, who received amino acid supplements postoperatively, have been excluded and one new patient added for this presentation. These changes were to ensure the pathological and nutritional comparability of the two groups.

Isotope studies of protein turnover have given conflicting evidence about the effects of a malignant tumour on the protein metabolism of the host. Leucine kinetics have been studied, as an index of protein turnover, using a well established methodology. Twenty patients were studied, five with benign disease of the colon, ten with localized malignant tumours of the large bowel, and five in whom there was evidence of metastatic disease from a colonic primary. No effect was observed on the leucine turnover of the patients that might be attributable to the presence or size of the tumour burden. It is suggested that some of the previously conflicting results may be attributable to variability in the experimental design, the heterogeneous patient groups studied and the methods used to express the results obtained.

Keywords: Protein turnover, leucine kinetics, malignant disease, tumour burden

Recently, practicable methods of measuring the dynamic aspects of protein metabolism have become available using both radioisotopes and stable isotopes as metabolic tracers. These methods have been used to investigate the inter-relationship between a malignant neoplasm and the nitrogen metabolism of the host organism. The first such study in humans[1] reported an increase in protein turnover which was proportional to the estimated tumour burden in patients with colorectal neoplasms. Later studies showed similar results in patients with a heterogeneous mix of tumours[2–4], in children with leukaemia and lymphoma[5] and in adults with non-oat cell carcinoma of the lung[6]. These results are in contrast to those in cachectic patients with lung tumours[7] and germ cell tumours[8]. Neither of these studies showed any effect of the tumour on host protein metabolism. Similarly, a study of patients before and after resection of colonic tumours failed to show any effect of tumour resection on protein turnover[9].

In an attempt to clarify these conflicting results a study was carried out in which leucine kinetics were measured in 20 patients, divided into four equal groups according to the colorectal pathology. One group had benign disease, two groups had 'localized' malignant disease (Dukes' A and B) and one group had metastatic disease.

Patients and methods

Details of the four groups are given in *Table 1* In each case the diagnosis and Dukes' classification were based on both clinical and histological results Nutritional status was assessed on the basis of body weight compared with standard values for height[10] and, biochemically, by measurement of serum albumin. Lean body mass (LBM) was calculated from the patient's height and weight using a standard formula method[11]

Leucine kinetics were measured both preoperatively and after a 12-h fast using a primed, constant infusion of L-[1-^{13}C]leucine. This methodology and its theoretical basis has previously been described in detail[12]. The central assumption is that in a steady state, leucine flux (Q) is equal to the sum of leucine released from protein (B) and leucine intake (I), which is in turn equal to the sum of leucine utilized in protein synthesis (S) and leucine oxidation (C), thus·

$$Q=B+I=S+C$$

The data were analysed by non-parametric statistics using the Mann–Whitney U test. The 95 per cent confidence intervals which have been advocated for use in reporting results[13] cannot be given for groups of five analysed non-parametrically as the range represents the 94 per cent confidence intervals

Results

The results for the anthropometric data and serum albumin levels on the four study groups are detailed in *Table 2*. There were no differences between the four groups with respect to weight, LBM or body weight as a percentage of ideal. However, despite well-maintained body weights and percentage weight for height, the patients with metastatic disease (group 4) had significantly lower serum albumin levels ($P<0.05$) than patients

Table 1 *Age, sex, diagnosis and classification in the four study groups*

	Age (years)	Diagnosis	Classification
Group 1			
Male	63	Diverticular disease	Benign
Female	72	Colonic adenoma	Benign
Male	64	Diverticular disease	Benign
Female	67	Diverticular disease	Benign

in any of the other groups (*Table 2*). Leucine flux, which in the fasted patient is equal to the release of the amino acid from protein, is shown in *Figure 1*. Although the lowest median value was in the group with benign disease (group 1) and the highest in the group with metastatic disease (group 4), these differences were not significant. Leucine utilization in protein synthesis (flux–oxidation) is shown in *Figure 2*, and once again there was no significant difference between the groups. Similar comparisons can be made for oxidation of leucine and for oxidation as a percentage of flux which gives a measurement of nitrogen reutilization. In each case there was no difference between the patients with benign as opposed to malignant disease or when comparisons were made within the groups with malignant disease.

Discussion

With the introduction of isotope tracer techniques and their use in clinical investigations of surgical patients there was an expectation that some of the controversies concerning nitrogen metabolism in the tumour-bearing patient might be resolved and that this would lead to a greater understanding of the pathogenesis of the cachectic syndrome commonly observed in advanced malignancy[1]. Such an understanding, it was suggested, was a prerequisite to developing therapeutic protocols to mitigate the metabolic effects of tumours[14]. In the nine published studies there is a dichotomy of opinion concerning the inter-relationship of tumour and host protein turnover.

As experience in general has increased with isotope studies of protein turnover it has become apparent that the data obtained are often predetermined by the conditions of the study and the experimental design. Furthermore, the interpretation of the experiment can be influenced by the method of expressing the results. One of the most potent influences on the measured values of protein turnover is nutritional status and the nutritional intake during the study. Nutrient withdrawal reduces protein synthesis by up to 40 per cent[15,16] while refeeding a malnourished patient will cause a marked stimulation[17]. The Newcastle study[1] concluded that protein turnover was increased in those patients with advanced tumours. However, considering the group as a whole, the lowest protein turnover rates were seen in the patients with metastatic disease. Only when the group was subdivided according to the presence or absence of 'anorexia' were differences apparent. Analysis of this study was further complicated by the use of a feeding regimen on the day of the isotope study that was standard for all patients; for the anorexic group this might have represented an increase on their prior intake. This study illustrates some of the problems in carrying out isotope studies of protein turnover in patients in whom the nutritional status and nutrient intake cannot be standardized. Objective measurements of intake can be made[18] and are preferable to the subjective assessment of anorexia. 'Refeeding' should be avoided as this will have an unpredictable, probably stimulating, effect on protein turnover.

Table 2 *Anthropometric data and serum albumin levels for the four study groups*

Study group	Weight (kg)	LBM (kg)	Body weight as percentage of ideal	Albumin (g l^{-1})
1 Benign	64 (54–70)	47 (45–47)	117 (80–130)	42 (35–43)
2 Dukes' A	69 (44–82)	49 (37–63)	109 (94–126)	41 (36–42)
3 Dukes' B	57 (42–89)	41 (36–62)	107 (87–145)	41 (39–42)
4 Metastases	58 (53–64)	41 (39–46)	109 (87–145)	36* (32–39)

Median values are given, with ranges in parentheses. LBM, Lean body mass; * $P<0.05$ compared with groups 1, 2 and 3

Many of the studies reported have examined both male and female patients. This, combined with the effects of variable weight loss and a wide age range, will result in a study population of widely differing body composition. While accurate measurement of total body nitrogen or potassium may not be possible, the practice of reporting results 'per patient'[8] is unacceptable unless two studies on the same patient are compared[9]. Even reporting results 'per unit whole body weight'[1–7] might introduce a bias towards higher figures for turnover in patients with low body fat stores and in children[5]. The use of some expression of metabolic mass or lean body weight is recommended to reduce these errors, and in the present study results were expressed 'per unit LBM'. Several of the reported series have included patients with malignant disease of differing types[2–5,7]. This adds to the problems of interpretation, and the practice of studying a defined 'pathological' population[6,8,9] is to be commended. Studies carried out under 'non-basal' conditions such as the postoperative period[4] or where unconventional expressions of tumour burden have been used[1] contribute to the difficulties in making comparisons between studies.

The present study of leucine kinetics has been carried out in a carefully defined group of patients requiring resectional surgery for benign or malignant disease of the large bowel. None of the patients gave a history of anorexia or weight loss. Isotope measurements were carried out after an overnight fast and there was no attempt to modify the voluntary nutritional intake in hospital. Tumour burden was defined according to the well established Dukes' classification plus an additional group with metastatic disease. The control group was important, and in this study control subjects were of similar age and undergoing surgery for benign colonic disease. Other studies have used laboratory volunteers[7] or patients who have had successful tumour resection as the control group[2], neither of which is ideal. One way of circumventing the problems of a control group is to carry out paired studies before and after the resection of a tumour[9]. Such a protocol is attractive but cannot be applied to patients with the more advanced tumours as there may be residual tumour even after surgical resection.

The present study shows no evidence of any alteration of leucine metabolism that might be attributed to the presence of a malignant tumour or that correlates with the estimated tumour burden. These conclusions support those made after investigations of patients with lung tumours[7], germ cell tumours[8] and in a previous study of adenocarcinoma of the colon[9]. Complexities of experimental design, heterogeneous patient populations and the use of unconventional or inappropriate methods of expression results may have contributed to the conflicting results previously reported.

Mr D. J. T. Webster

The development of myocutaneous flaps and other reconstructive procedures has made it possible to offer surgical palliation to many patients with advanced local recurrence of breast cancer who previously would have been regarded as untreatable. We present the results of excision of such recurrences in 42 patients treated from 1982 to 1986 after non-surgical measures had failed. Good palliation was achieved in all of the patients with acceptable morbidity. There was one death. Further local recurrences developed in 12 (29 per cent) patients, though none was painful or offensive. Thirteen patients remain alive and free from local disease; 17 patients remained free from local disease until they died.

Keywords: Breast cancer, local recurrence, surgery

Local recurrence after primary treatment of breast cancer may be only a minor problem in physical terms, but for a few unfortunate patients it becomes not just an unpleasant reminder of persisting disease but a progressive phenomenon leading to severe discomfort and deformity (*Figure 1*). The sheer size of the operative defect and difficulty in closing the axilla after excision of such tumours has often deterred surgical intervention in the past but with the development of myocutaneous and other local skin flaps it is possible to offer surgical treatment with primary wound closure to more of these patients.

We present our results of surgical treatment in patients with advanced local recurrence of breast cancer refractory to other forms of treatment.

Patients and methods

In the 5-year period from 1982 to 1986, 42 patients with painful or offensive local recurrence of breast cancer underwent radical excision of their breast or chest wall tumour, wound closure being aided by the use of either a rectus abdominis or latissimus dorsi myocutaneous flap, or a thoracoepigastric flap, with or without split skin grafting.

The mean age of the patients at the time of surgery for local recurrence was 56 years (range 28–86 years) and the mean period between primary treatment and salvage surgery was 4·5 years (range from 6 months to 26 years).

The primary treatment for breast cancer in these patients is shown in *Table 1*. The wide variation in treatment reflects the referral pattern to this secondary centre. There was wide variation in the stage at original presentation and in duration of disease.

Most of the patients received some form of treatment for their local recurrence before salvage surgery was contemplated. All but three of the 42 patients had undergone radiotherapy to the limits of local skin tolerance and, of these, 23 had also received hormonal treatment and 21 had received cytotoxic chemotherapy. In addition to progressive local disease, seven of the patients were known to have systemic metastases but were considered suitable for intervention because their distant disease was static or progressing slowly.

Local recurrences could be divided into two main forms: (1) patients with a single tumour mass, usually in a conserved breast, and (2) those who had infiltrating ulcerative tumours, a proportion of which were surrounded by multiple skin nodules (*Figures 2* and *3*). *Table 2* gives a summary of the range of tumour involvement and ulceration. In patients with multiple nodules, the largest diameter of clinically involved skin was recorded.

Surgical treatment for local recurrence entailed excision of all palpable tumour with a minimum margin of surrounding skin of 5 cm. In patients who had previously undergone conservative treatment, a Halsted mastectomy was performed tailoring the skin incision to the position of the recurrent tumour. For the remainder, the tumour was excised with underlying muscle and incorporating any ribs to which there appeared to be periosteal or bony fixation. In those patients who required rib resection and in whom the parietal pleura was breached (five cases), a chest drain was inserted and the chest wall defect was plugged with a portion of the muscle from the myocutaneous flap used for wound closure. Antibiotic prophylaxis was given as a single dose of metronidazole plus a cephalosporin at induction of anaesthesia.

Myocutaneous[1,2] and thoracoepigastric[3] flaps were raised according to techniques previously described and were sutured into the chest wall defect using chromic catgut or other absorbable sutures to anchor the muscle to chest wall, and interrupted silk sutures to the skin in early cases or subcuticular Prolene® (Ethicon Ltd., Edinburgh, UK) sutures later in the series.

Twenty-two latissimus dorsi flaps, 16 rectus abdominis and five thoracoepigastric flaps were employed to aid in wound closure, and in one patient split skin grafts alone were used. In one patient both a latissimus dorsi and a thoracoepigastric flap were required to obtain

complete skin cover, and in one further case a latissimus flap was used to replace a rectus flap which had failed. Three patients in the latissimus flap group, two in the rectus abdominis group, and one of the patients in whom a thoracoepigastric flap was employed required split skin grafting in addition because of the extent of the operative defect.

Results

Hospital stay and wound healing

Of the 42 patients in this series 30 required hospitalization for less than 3 weeks. In the 12 remaining cases hospital stay was prolonged to 4–16 weeks by delayed wound healing. Despite heavy preoperative bacterial colonization, wound infections were restricted to cellulitis which responded to antibiotic therapy; most of the delay in wound healing resulted from either failure of a portion of a skin flap or breakdown of a suture line involving previously irradiated skin under tension.

Complete wound healing was eventually achieved in all but two of the patients after salvage surgery. In the first of these, a mammary prosthesis inserted beneath a latissimus dorsi flap had to be removed because of infection, and the resulting wound was healing by granulation at the time of death only 3 months postoperatively. In the second case a suture line involving an area of previously irradiated skin dehisced, leaving a wide defect which was granulating and painless with a Silastic (Dow Corning, Reading, UK) foam dressing but which remained incompletely healed at the time of the patient's death 5 months after surgery.

Flap complications

Six patients (14 per cent) suffered complications relating to the skin flap; four of these (two rectus abdominis and two latissimus dorsi flaps) involved necrosis of the distal 25–30 per cent of the skin island, requiring excision and split skin grafting to the defect. The other two patients each initially had a rectus abdominis flap which underwent total necrosis, and in one of these cases the resulting defect (which included segments of two ribs) was covered with a latissimus dorsi flap. In this latter patient the skin island of the latissimus flap also necrosed although the muscle survived allowing later split skin grafting.

Other postoperative morbidity and mortality

With the exception of the wound problems already recorded, postoperative morbidity was limited to respiratory atelectasis or infection treated by mobilization, physiotherapy and antibiotics. No patient required intensive care after operation.

One patient died in hospital 4 weeks after salvage surgery, the cause of death being bronchopneumonia exacerbated by reactive depression and immobility.

Further local recurrences

Twelve of the surviving patients (29 per cent) developed further local recurrence after salvage surgery, although none of these recurrences was massive or painful. In three cases the further recurrence was limited enough to be excised locally. These patients remain alive; two of them are currently free from local disease.

Only two of the 17 (12 per cent) patients with a single mass of recurrent tumour developed further local disease after salvage surgery, but ten (40 per cent) of 25 patients with multiple tumour nodules suffered a further recurrence.

Survival after salvage surgery

Twenty-nine patients (69 per cent) died between 3 months and 6 years after salvage surgery (mean 1·6 years). Thirteen patients (31 per cent) remain alive 1–4 years after excision of local recurrence, and only one has evidence of chest wall disease at present.

Discussion

It is difficult to estimate the rate of local recurrences in the population from which these patients come as a wide variety of treatments is used in the region for both early cancer and advanced disease, and we presume that some patients have been treated by other surgeons. We have not treated surgically all those referred to us because we have thought the disease already too extensive or spreading so rapidly that early recurrence seemed inevitable—some patients have also declined the offer of surgery.

The options in the situation where the disease persists after previous radiotherapy, hormonal therapy and chemotherapy

are limited to palliative dressings, attempts to limit odour and surgery.

Our experience confirms that the use of myocutaneous flaps enables closure of the very extensive wounds resulting from excision of advanced breast and chest wall recurrences, with the particular benefit of the ability to cover any axillary defects. Otherwise, many of these defects could only have been covered by skin grafts or left to heal by granulation with the hazards of exposure of axillary structures and greatly prolonged wound healing.

The alternative approach[4], which we have not found necessary, is to place split skin grafts on to transposed omentum. This adds the risk of intra-abdominal complications as well as being cosmetically and functionally less acceptable to the patients.

The cosmetic results of our procedure were inevitably a compromise, but all patients showed an improvement from preoperative appearances (*Figure 4a* and *4b*) and none expressed regret at undergoing surgery.

The 25 per cent flap complication rate for rectus abdominis flaps (12 per cent partial plus 12 per cent total necrosis; four cases) and 14 per cent for latissimus dorsi flaps (9 per cent partial, 4 per cent total necrosis; three cases) encountered in this series are higher than we have experienced when employing these flaps for breast reconstruction after primary treatment of breast cancer[5]. Whilst these failures may have been partly related to the advanced age and poor general condition of patients undergoing salvage surgery, it is also possible that previous radiotherapy to the pedicle of a myocutaneous flap could have been involved in some of our complications. In particular, it was noted at the time of raising the only latissimus dorsi flap which underwent total necrosis that there was very marked axillary fibrosis following high-dose radiotherapy. Recently we have found Doppler ultrasound to be of value in confirming the patency of vessels in the flap pedicle before surgery.

The pattern of recurrence allows some prediction of subsequent outcome: patients with multiple intradermal nodules are more likely to develop further trouble than those with a large ulcerating solitary mass.

When local recurrence is likely, consideration of adjuvant therapy is appropriate but in such heavily pretreated patients an acceptable manoeuvre may not be available.

We feel that these results justify the decision to carry out extensive surgery in these patients with advanced locally recurrent breast cancer and would advocate the use of salvage surgery in any patient with distressing local disease who fails to respond to more conservative measures.

Acute ischaemia of the upper limb compared with acute lower limb ischaemia; a 5-year review

P. A. Stonebridge, A. E. Clason, A. J. Duncan, B. Nolan, A. McL. Jenkins and C. V. Ruckley

Vascular Surgery Unit, The Royal Infirmary, Edinburgh, UK
Correspondence to:
Mr P. A. Stonebridge

A series of 61 patients with acute upper limb ischaemia treated over a 5-year period is analysed and compared with patients presenting with acute lower limb ischaemia during the same period. The mean age was 74 years with a female to male ratio of 2·2:1. Eighty-two per cent were treated by operation. Three patients died and no survivors required a major or minor limb amputation, in contrast to a 5 per cent major limb amputation rate in patients with acute lower limb ischaemia. Mortality for upper limb ischaemia was 5 per cent compared with a 30 per cent mortality rate in patients with acute lower limb ischaemia in whom cardiopulmonary debility (New York Heart Association score 3–4) was significantly greater.

Keywords: Acute upper limb ischaemia, acute lower limb ischaemia, morbidity, mortality

Acute ischaemia of the upper extremity is uncommon, accounting for only 15–18 per cent of acute ischaemic episodes of the extremities[1,2]. Nevertheless, when it does occur arm ischaemia may seriously jeopardize the livelihood and independence of the individual. Our recent experience of acute upper limb ischaemia in a regional vascular referral centre has been reviewed, and a comparison has been made with acute ischaemia of the lower limb.

Patients and methods

The medical records of patients presenting to the Vascular Surgery Unit of the Royal Infirmary of Edinburgh with acute upper limb ischaemia during the 5-year period 1983–87 were examined. The unit is a regional referral centre and serves a population of approximately 1·2 million. Patients were identified from ward discharge summaries, operating theatre registers and annual audit reports. Patients who presented with ischaemia after trauma or previous arterial reconstruction were not included in the study. Patients were treated either with conventional balloon catheter embolectomy or with intravenous heparin or thrombolytic therapy. A comparison with a previously analysed series of patients presenting with acute ischaemia of the lower limb in the same period was made.

Results

Sixty-one patients with acute ischaemia of the upper limb were identified with a total of 84 ischaemic episodes and compared with 204 patients presenting with acute lower limb ischaemia during the same period. The patient characteristics are shown in *Table 1*. Of the 61 patients with upper limb ischaemia nine patients experienced synchronous emboli to 12 other sites. Eleven patients were managed conservatively with either intravenous heparin or intravenous streptokinase, while 50 patients underwent operation. Three patients required additional synchronous vascular reconstructive procedures, two brachiobrachial vein bypass grafts for operative iatrogenic injuries and one axillobrachial artery polytetrafluoroethylene graft for an axillary artery stenosis. Eighty-seven per cent of patients received intravenous heparin and 79 per cent were treated with oral anticoagulants. Seven patients (11 per cent) had additional episodes of embolism while in hospital. Twenty patients (33 per cent) had a previous history of arterial embolus. Forty-three patients (70 per cent) had clinical evidence of a possible cardiac origin of the embolus (*Table 1*). The sites and levels of the ischaemic episodes are shown in *Table 2*.

Five of 25 echocardiograms performed showed intracardiac thrombus, but only one of these re-embolized, as did one in a patient with a negative scan. The outcome appears uninfluenced by the duration of symptoms, level of occlusion, pre-existing peripheral arterial disease, cardiopulmonary function (New York Heart Association (NYHA)) score* or recent myocardial infarction.

Table 1 *Patient characteristics*

Values in parentheses are percentages

Only one factor was associated with a poor outcome and that was repeated embolism. Two of the seven patients with evidence of further recurrence died as a result of the further embolism (the third death was due to a pulmonary embolus), despite the fact that all were anticoagulated.

* *NYHA score, a measure of cardiopulmonary debility according to the degree of symptoms of angina and/or breathlessness: class 1, no symptoms, class 2, symptoms with more than usual activity, class 3, symptoms with usual activity, and class 4, symptoms at rest*

0007-1323/89/050515-02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

The mortality rate was 5 per cent (three patients), with a successful outcome (return to full function of the upper limb) in all 58 who survived.

Discussion

Acute ischaemia of the upper limb is uncommon (accounting for only 23 per cent of all cases of acute limb ischaemia in this study). In the present study 84 per cent of upper limb emboli were small enough to pass beyond the subclavian artery, but only 5 per cent of lower limb emboli reached the popliteal artery.

As in previous series[3–5] 70 per cent of patients had a possible cardiac origin for their embolus. All seven of those who had further emboli (11 per cent) were fully anticoagulated and fibrillating at the time of recurrence, while three had had a myocardial infarction within the two previous weeks. Ricotta *et al.*[4] reported a 33 per cent incidence of recurrence of embolism in patients who were not anticoagulated.

As previously reported[6,7] a higher mortality rate was found to be associated with re-embolization Therefore adequate anticoagulation of patients after embolectomy appears to be an important facet of management, and should not be based on the results of echocardiography, but rather on clinical assessment

Operative intervention for upper limb embolism has been shown to be superior to medical management[8] Even in an apparently viable limb the operative removal of an embolus is preferable in order to protect the proximal collateral supply on which the viability of the limb may depend

The low mortality in this series contrasts with the 12 per cent mortality rate due largely to cardiac causes which has been reported by other authors[5,6]. There were no cases of distal gangrene and no amputations were required, in contrast to patients with lower limb ischaemia in whom 5 per cent of survivors required amputations. Haemovici[5] in his personal series quotes a 78 9 per cent overall limb salvage rate, with a 7 per cent major amputation rate in survivors. The difference in morbidity may be due in part to a much higher incidence of proximal upper limb atherosclerotic disease. Ricotta *et al*[4] suggest an 18 per cent incidence of proximal disease in their series of upper limb ischaemia In this study proximal disease is a factor in only one of the 50 patients who underwent operation.

Comparison between upper and lower limb acute ischaemia (*Table 1*) reveals marked differences in terms of patient characteristics, morbidity and mortality. There are significantly fewer patients in the upper limb group who had evidence of generalized or localized occlusive arterial disease. There is a greater proportion of women with acute upper limb ischaemia. In the lower limb group there was a higher proportion of patients with severe cardiopulmonary symptoms although the average age of both groups was similar. The incidence of either atrial fibrillation or recent myocardial infarction was similar in both groups and it is reasonable to assume the incidence of cardiac emboli also to be similar. Differences in amputation rate have already been noted

The mortality rates are significantly different, with 5 per cent in the upper limb group and 30 per cent in the lower limb group ($\chi^2 = 15\ 4$, $P < 0{\cdot}001$). This may be accounted for by a number of factors: the size of the embolus, the presence of obliterative arterial disease in the lower limb group, and possibly a lesser risk of toxaemia on upper limb revascularization.

Our results show that operative treatment is a safe and effective means of management of acute upper limb ischaemia, the only contraindication to surgical treatment being a moribund patient or a limb beyond salvage.

Incidence of septic and thromboembolic-related deaths after splenectomy in adults

W. Pimpl, O. Dapunt, H. Kaindl and J. Thalhamer

1st Surgical Department, Ludwig-Boltzmann Institute for Experimental and Gastroenterological Surgery, Landeskrankenanstalten Salzburg, Austria

Correspondence to:
Dr W Pimpl, I. Chirurgische Abteilung, Landeskrankenanstalten Salzburg, Muellner Hauptstrasse 48, A-5020 Salzburg, Austria

In a review of 37 012 autopsies over the last 20 years 202 deceased adults who had had a splenectomy were investigated. The incidence of infections and thromboembolic complications related to death in these patients was compared with that of a matched deceased population (n = *403) who had not undergone splenectomy. Death-related pneumonia was diagnosed frequently in the splenectomy group and to a lesser extent in the control group (57·9* versus *24·1 per cent,* $P<0{\cdot}001$*). Lethal sepsis with multiple organ failure occurred in 6·9 per cent of the splenectomy group and in 1·5 per cent of the controls* ($P<0{\cdot}001$)*. Purulent pyelonephritis was observed in 7·9 per cent of the splenectomy group and was significantly more frequent than in the control group with its rate of 2·2 per cent* ($P<0{\cdot}001$)*. Finally, pulmonary embolism was the major or a contributory cause of death more often in the splenectomy group than in the control group (35·6* versus *9·7 per cent,* $P<0{\cdot}001$)*. We conclude that splenectomy generates a considerable life-long risk of severe infection and of thromboembolism.*

Keywords: Splenectomy, thromboembolism, sepsis, autopsy

During the past decade, increased rates of early and late septic complications after splenectomy have been reported[1–7]. In 2–5 per cent of these cases a life-long risk of fatal sepsis has been assumed[8–18]. In addition, thromboembolic complications occur more frequently in asplenic individuals compared with a healthy population because of impaired platelet function[4,7,13,19]. These facts have encouraged attempts to repair the traumatically ruptured spleen or to preserve splenic function by reimplanting splenic tissue when splenectomy was unavoidable[20–29]. As some of these techniques require great technical skill and may extend the time of the operation, it can be harmful to attempt splenic preservation unless there are clearly defined benefits.

As there is still controversy in the literature concerning the risks of splenectomy, especially years after the operation, the optimal surgical management of ruptured spleen remains an open question. In order to define the true long-term risks of splenectomy, rather than examining complications of the early and late postoperative period, we have reviewed all autopsy records of the last 20 years at our institution to identify the causes of death in previously splenectomized adult patients and have compared these with a matched population. Legislation in our country ensures that nearly every patient who dies in our hospitals and those who die for unclear reasons at home have an autopsy. Therefore, and in contrast to other published papers, we should be able to define precisely the incidence of lethal postsplenectomy sequelae.

Patients and methods

The data were collected by retrospective review of 37 012 autopsies of adult patients who died in one of the six hospitals in Salzburg (a town with approximately 140 000 inhabitants) or who died at home for unclear reasons. Post-mortem examination of these patients was performed at the Institute of Pathological Anatomy (Professor Dr J. Thurner, Landeskrankenanstalten Salzburg).

The study series consisted of 202 adults (148 men, 54 women, mean age (± s.d.) 59·1 ± 15·9 years) who underwent splenectomy for various indications, as outlined in *Table 1*. The patients in the trauma group ($n=61$, 30·2 per cent) could be divided on the basis of three types of injury: isolated splenic rupture (type I), splenic injury plus thoracic trauma (type II) and splenic rupture plus head injury (type III).

The iatrogenic group ($n=63$, 31·2 per cent) comprised patients with splenic injuries sustained during abdominal surgery for non-malignant diseases.

Splenectomy for oncological reasons, such as gastric or colonic cancer, was performed in 56 patients (27·7 per cent).

In the final group, splenectomy was indicated because of haematological disorders ($n=22$, 10·9 per cent).

In order to evaluate postsplenectomy sequelae for the early postoperative period as well as for the later period, the patients were divided into two subgroups: those who died within 3 months of splenectomy and those who died more than 3 months after splenectomy.

As a control group we chose 403 patients (294 men, 109 women, mean age (± s.d.) 60·3 ± 16·6 years) who, during the same period, had comparable trauma or who underwent similar surgery for malignant or non-malignant diseases (*Table 1*).

In both groups, patients with lethal head trauma or exsanguinating injuries were excluded.

In our retrospective investigation we compared the incidences of the major causes of death in both groups. Furthermore, we tried to obtain information from the autopsy records about the rate of septic and thromboembolic complications with and without splenectomy. These specific complications have been chosen because their incidence has been reported to be more frequent in asplenic individuals[2,4,6,14,19].

In order to provide a good statistical comparison, special care was taken to ensure that the clinical data matched as well as possible. For the statistical comparison we used a two-tailed χ^2 test with Yates' correction (significance level, $P<0{\cdot}05$).

Results

Time period between splenectomy and death

One hundred and two (50·5 per cent) of the patients in the splenectomy group died within 3 months of the operation. A further 28·2 per cent of the patients died within the first three postoperative years. Subsequently, the number of deaths decreased as outlined in *Table 2*.

Major causes of death

The major causes of death are outlined in *Table 3*. In the splenectomy group the leading cause of death was pneumonia (50·5 *versus* 23·6 per cent in the control group, $P<0{\cdot}001$). Congestive cardiomyopathy, on the other hand, led to death significantly more often in the control group (29·3 *versus*

*Type I, isolated splenic rupture (*versus* hepatic tears in the control group), type II, type I plus thoracic trauma, type III, type I plus head injury

8·4 per cent). In 16·3 per cent of the patients pulmonary embolism was lethal after splenectomy, compared with 4·7 per cent of the controls. This difference was highly significant ($P<0{\cdot}001$). In addition the incidence of sepsis was significantly higher in the splenectomy group ($P<0{\cdot}001$). In the control group advanced malignancies were significantly more often the major cause of death.

For all other specified causes of death, including myocardial infarction, there was no significant difference betwen the two groups.

Death-related complications

Severe pneumonia Severe pneumonia was diagnosed frequently in the splenectomy group and to a lesser extent in the control group (57·9 *versus* 24·1 per cent, $P<0{\cdot}001$; *Table 4*). A statistical difference between the two groups could be demonstrated for the whole series as well as for both early and late postoperative periods (*Table 5*) The rate of pneumonia was significantly higher in splenectomized patients in all disease subgroups with the exception of the therapeutic one (*Table 6*).

Sepsis. Lethal sepsis with multiple organ failure was diagnosed in 14 of 202 splenectomized patients (6·9 per cent), and was significantly more frequent than in the control group with six out of 403 patients (1·5 per cent; *Table 4*). Whereas the incidence of sepsis in the early postoperative period was similar in the two groups, after 3 months sepsis was more common in the splenectomized patients ($P<0{\cdot}001$; *Table 5*).

There were no statistical differences in the incidence of sepsis between the various disease subgroups, except the iatrogenic subgroup ($P<0{\cdot}03$; *Table 6*).

Purulent pyelonephritis. A purulent pyelonephritis was observed as the cause of death in 7·9 per cent of the splenectomy group, which was significantly more frequent than in the control group where it was 2·2 per cent (*Table 4*) Nearly all cases of pyelonephritis occurred in patients more than 3 months after splenectomy (*Table 5*). No statistical difference could be demonstrated for the subgroups between splenectomy patients and controls (except in the oncological subgroup; $P<0{\cdot}03$; *Table 6*).

Purulent meningitis Lethal meningitis was diagnosed in 0·5 per cent of the splenectomy group and in 1·0 per cent of the controls (difference not significant; *Table 4*).

Massive pulmonary embolism. Massive embolism of one, or even several branches, of the pulmonary arteries occurred significantly more often in splenectomized patients than in controls (*Table 4*). Furthermore, this statistical difference could be demonstrated for all investigated subgroups (*Tables 5* and *6*).

Discussion

In keeping with other published series our data show that splenectomy carries a considerable risk of infectious and thromboembolic complications, even years after the operation.

Concerning the major causes of death, our study identified that significantly more patients died from pneumonia, sepsis

Table 2 *Period between splenectomy and death in 202 patients*

and pulmonary embolism in the splenectomy group than in the control group. No significantly higher incidence of myocardial infarction was found in the asplenic group. However, congestive cardiomyopathies and advanced malignancies were observed significantly more often in the controls.

With regard to the period between splenectomy and death, 50·4 per cent of the patients died within 3 months of the operation. The death rate decreased in the following years and was only 3·5 per cent in the fourth postoperative year. This observation is consistent with those of other authors[2,4,5,7] and may be due to the fact that many functions of the spleen are eventually balanced by other immunocompetent organs. Therefore, we can state that the highest risk of lethal sequelae after splenectomy can be expected during the first three postoperative years with a maximum in the immediate postoperative period.

Infectious complications

Most of the published series deal with infectious complications in the period immediately after splenectomy[1,2,4,7,22]. Infectious complications include urinary tract infections, pneumonia or sepsis, particularly operation-related sequelae such as wound abscesses or left-sided subphrenic collections. Francke *et al.*[2] described in their review a rate of 1–55 per cent of infectious complications and a mortality rate lower than 4 per cent. Obviously these rates are much greater in high-risk groups such as infants, immunocompromised patients or those with malignancies than in adults with elective splenectomy or splenectomy due to trauma[1,2,4,6,7].

In order to estimate the true risk of splenectomy it is therefore necessary to describe the morbidity and mortality with regard to the preoperative immunological status of the patient and the reason for the splenectomy. Ziemski *et al*[7] reported, in a recently published series comprising 688 splenectomized patients, overall morbidity and mortality rates of 51·1 and 4·7 per cent, respectively, for the early postoperative period. When the indication for surgery was taken into account, the mortality rate after splenectomy for trauma or primary benign splenic diseases was less than 1·0 per cent and increased to 8·4 per cent if the underlying disorder led to secondary hypersplenism. Left-sided pneumonia was observed most frequently in 20·4 per cent, which is comparable to other rates reported in the literature[1,4,7,22].

The rate of sepsis in the paediatric series ranged from 1·5 per cent (trauma) to 16·0 per cent (splenectomy for thalassaemia)[2,11,18]. Corresponding data for adults are much lower, revealing an overall mortality rate of less than 3 per cent for all indication groups[2,6,7,9,15,17].

In our series the most frequent cause of death within 3 months of splenectomy was pneumonia and the rate was almost three times higher than in the control group. Other infectious complications, within 3 months of splenectomy, were not observed to be more frequent in the splenectomized group compared with the non-splenectomized group.

Concerning late infectious complications after splenectomy, there are only a few reports in the literature and they comprise mainly data of postsplenectomy sepsis[1,2,4,7]. The main problem with these reports is that the periods of observation after splenectomy differ. Therefore the 'life-long' risk of splenectomy is still controversial. Furthermore, there exist only a few publications that compare splenectomized series with comparable control groups[1,11,27]. Carlstedt *et al*[1] described retrospectively a statistically higher rate of infectious complications in patients from whom the incidentally injured spleen had to be removed during abdominal operation than in a control group of patients undergoing proximal selective vagotomy with follow-up 8 years after the operation.

There exist only two prospective studies comparing the complications of patients after splenectomy with those of patients in whom the spleen could be salvaged. Green *et al.*[11] showed that the incidence of postsplenectomy sepsis in paediatric patients was 11 per cent in their small series of splenectomies, whereas the control group revealed no septic complications. Traub *et al.*[27] concluded in their recent report that reticuloendothelial function was better preserved after partial splenectomy than in autologous spleen transplantation, but that autotransplantation was superior to total splenectomy.

In the late postoperative period we demonstrated that the risk of severe pneumonia was two times higher in splenectomized patients than in the control group patients. The incidences of purulent pyelonephritis and of sepsis was also significantly higher in splenectomized patients than in the controls in the late postoperative period However, regarding the sepsis cases in our study, it is not possible to classify them as overwhelming post-splenectomy infection syndromes as this diagnosis cannot be established from a retrospective review of autopsy records without knowledge of the clinical course of the patients

Thromboembolic complications

Ziemski *et al* [7] published an incidence of pulmonary embolism in 3 per cent of patients during the early postoperative period after splenectomy. There have been no published comparative studies for thromboembolic complications in the late postoperative period since the extensive report of Robinette and Fraumeni[19], who did not show a significantly higher frequency of this complication in asplenic individuals. This fact is surprising, and contrasts with our results, as splenectomy causes a hypercoagulable state due to an increase of platelets in the peripheral blood count in the early postoperative period Several weeks after splenectomy the pooling of platelets occurs in other organs (e.g. liver), but a life-long relative increase of immature platelets in the peripheral blood may be responsible for thromboembolic disorders even years after splenectomy[29].

In our study pulmonary embolism was the most significant complication after splenectomy in all subgroups.

Myocardial infarction

In contrast to Robinette and Fraumeni[19] we did not demonstrate a significantly higher risk for myocardial infarction in the asplenic group compared with the controls This fact may be due to the small number of patients who survived for more than 3 months after splenectomy in our study.

Recurrence of gastrointestinal malignancies

In our series significantly more patients in the control group died from advanced malignancies compared with the splenectomy group. Unfortunately it is not possible to draw any conclusions about the rates of cancer recurrence in our patients from the autopsy records

Clinical consequences

In summary, we have to underline the opinion of Green *et al.*[11] that splenectomy can no longer be considered a safe operation. The following risks can be predicted. For elective splenectomy the overall risks of severe pneumonia and of pulmonary embolism can be estimated to be two and four times higher, respectively, than for a comparable operation without splenectomy Furthermore, there is a significant risk of lethal sepsis, even years after splenectomy. However, the highest rate (78·7 per cent) of these complications occurs within the first three postoperative years. Therefore, perioperative antibiotic prophylaxis (broad-spectrum penicillin plus aminoglycoside)[30] and preoperative pneumococcal vaccination[29] for patients of every age are advised. Exact preoperative diagnosis of the individual thromboembolic risk (history, concomitant diseases, laboratory tests, phlebography), perioperative intermittent compression boots, and heparin are strongly recommended. Postoperatively these patients should be encouraged to take a broad-spectrum penicillin and a low-dose aspirin for at least 3 years.

In cases of traumatic or incidental spleen injury during abdominal surgery, orthotopic spleen preservation should be attempted. Surgeons should choose the technique with which they are most familiar. In some cases, where the salvage of the massively ruptured spleen is not possible and when the abdomen is not contaminated, the reimplantation of splenic tissue into the greater omentum should be considered.

The patient who undergoes spleen autotransplantation should be treated in the same manner as the patient who has undergone splenectomy[24]. This includes long-term penicillin treatment as well as pneumococcal vaccination. The rationale for these requirements is the unreliability of autotransplants in the prevention of septic complications and the increase in antibody titres of pneumococcal vaccine seen in autotransplant patients[31].

We conclude that splenectomy carries an increased short- and long-term risk of both infectious and thromboembolic complications, and that whenever possible the procedure should be avoided.

Operative mortality after perforated peptic ulcer

A. B. S. Ball, P. A. Thomas and S. J. Evans

Department of Surgery, Whipps Cross Hospital,
Leytonstone, London E11 1NR, UK
Correspondence to: Mr P. A. Thomas

The mortality rate associated with the surgical treatment of perforated peptic ulcer is reported to be under 10 per cent[1–3]. However, the Hospital In-patient Enquiry (HIPE) has revealed that the proportion of older patients (>60 years of age) admitted to hospital with a diagnosis of perforated peptic ulcer is rising[4]. A retrospective study of patients with perforated peptic ulcers who were operated on at Whipps Cross Hospital over a period of 3 years has been undertaken to examine the current age distribution of such patients and its relationship to the immediate postoperative prognosis.

Patients and methods

The medical notes of three consultants' patients undergoing surgery for perforated peptic ulcer between September 1984 and September 1987 were reviewed. Details of patients whose perforation was simply over-sewn and who died postoperatively were compared with those of patients in the same age group who survived with respect to 15 different variables (*Table 1*). Statistical comparisons were performed with Fisher's exact test. Differences were taken to be significant at the 5 per cent level

Table 1 *Variables included in analysis*

Preoperative serum Na^+
Preoperative serum K^+
Preoperative blood concentration
Duration of surgery

* A medical condition other than peptic ulceration requiring medical supervision and/or admission to hospital within 3 years of ulcer perforation; † systolic blood pressure <100 mmHg and/or condition requiring preoperative central venous pressure line

Results

Between September 1984 and September 1987, 36 patients were operated on for perforated peptic ulcer (26 duodenal ulcers, ten gastric ulcers). More than half were ≥70 years of age. Eleven (31 per cent) died in the postoperative period (*Figure 1*)

Twenty-nine patients (81 per cent) underwent simple over-sewing of the perforation (*Table 2*). The median age of these patients was 72 years (range 19–91 years). Eight (28 per cent) died in the postoperative period (1–35 days after surgery). Four died from bronchopneumonia, two from septicaemia, one from myocardial infarction and one from acute renal failure The postoperative mortality rate of patients <70 years who underwent simple over-sew was zero compared with 47 per cent

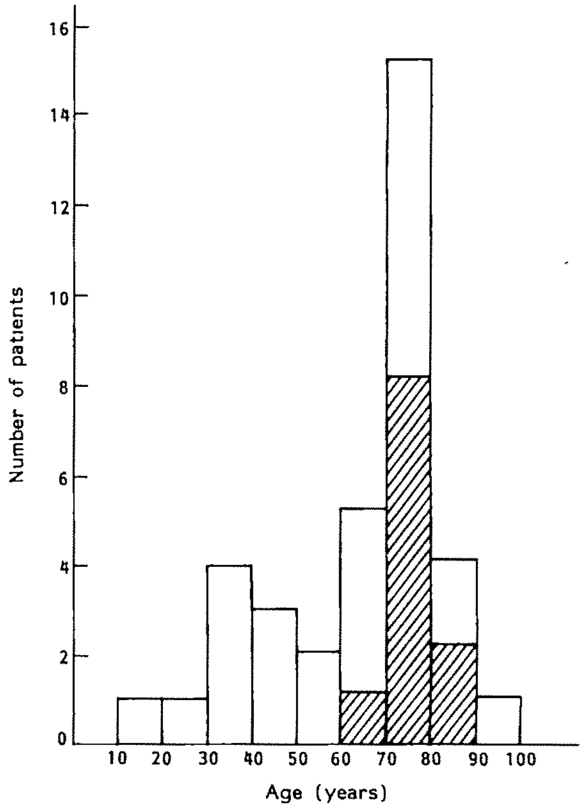

Figure 1 *Age distribution of mortality in 36 patients with perforated peptic ulcer.* ■, *Number of patients who died*

Table 2 *Characteristics of patients having simple oversew*

Age (years)	Sex: Men	Sex: Women	Duodenal ulcer	Gastric ulcer
<70	8	4	12	0
≥70	9	8	10	7

0007–1323/89/050521–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

in those $\geqslant 70$ years ($P<0{\cdot}02$). The patients <70 years old all had duodenal ulcers while 41 per cent of patients $\geqslant 70$ years had gastric ulcers ($P<0{\cdot}05$).

Among patients $\geqslant 70$ years of age who were clinically shocked on admission, the mortality rate after simple over-sew was 100 per cent compared with 25 per cent in those who were not shocked ($P<0{\cdot}02$) However, preoperative shock was only present in 63 per cent of the patients who died.

Among those patients $\geqslant 70$ years of age whose preoperative blood urea exceeded 15 mmol/l (twice the upper limit of normal), the postoperative mortality rate was 100 per cent compared with only 10 per cent in those with a lower blood urea ($P<0{\cdot}01$). Eighty-eight per cent of patients 70 years or older who died had a preoperative blood urea above 15 mmol/l while all the survivors had a lower blood urea preoperatively. There was no significant correlation between the age and the preoperative blood urea of patients in this study

There was no significant difference between the mortality rates of patients $\geqslant 70$ years with duodenal ulcers and that of patients $\geqslant 70$ years with gastric ulcers, and other variables such as the presence of comorbid conditions did not distinguish between patients $\geqslant 70$ years who died and those who survived

Discussion

The HIPE analysis indicates that the proportion of elderly patients admitted to hospital with perforated peptic ulcer is increasing[4]. This trend was evident in our series which revealed a high mortality among patients $\geqslant 70$ years with either duodenal ulcer or gastric ulcer even after simple over-sew. A similar observation among patients with perforated gastric ulcer has been reported recently[5]. Although the mortality of patients $\geqslant 70$ years was high, more than half survived, indicating that other factors contributed to mortality.

Preoperative shock was associated with a mortality rate of 100 per cent in patients $\geqslant 70$ years, but over a third of the patients who died were not clinically shocked on admission. A preoperative blood urea above 15 mmol/l in patients $\geqslant 70$ years was also associated with a postoperative mortality rate of 100 per cent but was present in a higher proportion (88 per cent) of those who died and was thus more specific.

It is unlikely that any single factor determines the outcome of surgery for perforated peptic ulcer. However, the identification of any group of patients in whom surgery is accompanied by an extremely high risk of postoperative mortality makes it important to consider alternative forms of treatment in these cases.

Conservative management for perforated peptic ulcer is now seldom undertaken. Nevertheless, previous studies have reported that the mortality rate with conservative treatment is remarkably low[6–9] Unfortunately, no studies have been properly controlled, and none has examined the role of conservative treatment specifically in elderly patients

This study suggests that there is a definable group of elderly patients in whom surgery is associated with a high risk of postoperative mortality In view of the increasing proportion of elderly patients admitted with perforated peptic ulcers, we suggest there is an urgent need to identify this group more precisely. If these patients can be accurately selected, the role of definitive, or preliminary expectant, conservative treatment in such cases should be re-evaluated

Blood transfusion in colorectal cancer

M. C. Crowson, M. T. Hallissey, R. S. Kiff*, R. D. Kingston* and J. W. L. Fielding

*Surgical Immunology Unit, Queen Elizabeth Hospital, Birmingham and *Department of Clinical Studies, Park Hospital, Manchester, UK*

Correspondence to: Mr M. T Hallissey

Blood transfusion has been reported to improve graft survival following cadaveric renal transplantation as a result of an alteration in immunoresponsiveness[1]. Gant suggested that this effect may be detrimental to patients undergoing treatment for malignant disease[2]. Retrospective studies of perioperative transfusion have produced conflicting results[3–5].

Blood transfusion may simply be a marker of other recognized prognostic factors. To assess the effect of blood transfusion on the time to recurrence and duration of survival, independent of the known prognostic variables, a group of patients under prospective follow-up has been studied.

Patients and methods

The patients studied underwent surgery in hospitals in the West Midlands and North West regions of the UK between 1981 and 1983. All the patients were under the age of 80 years, had a modified Karnofsky score[6] of between 0 and 3 and had modified Dukes' B or C colorectal adenocarcinoma All operations were judged, by the operating surgeon, to be potentially curative. Data were collected prospectively for the recognized prognostic variables, as follows. age, sex, performance score, obstruction, heparin, site, Dukes' classification, histological grade, depth of penetration, circumferential involvement, haemoglobin at entry

Patients were followed up with full clinical and biochemical assessment every 3 months until death, or for 5 years Additional investigation for recurrent disease was undertaken when clinically indicated Tumour recurrence was diagnosed on clinical, radiological, ultrasound or pathological evidence of dissemination Time to recurrence and duration of survival were calculated from the date of resection

Blood transfusion details were obtained retrospectively by examination of the notes and blood transfusion records. The timing of

n.s., Not significant

transfusion was classified as preoperative (up to 30 days before surgery), perioperative (the 24 h during and after the operation) and postoperative

The effect of blood transfusion and the other prognostic factors have been assessed using log rank analysis To identify those factors having an independent effect on survival, a multiple regression analysis using Cox's method was performed Subset analysis has been undertaken by tumour site and timing of transfusion

Results

Of the 525 patients studied, 373 had received a blood transfusion and 152 had not. These groups were comparable for all the recognized prognostic variables. Only preoperative haemoglobin differed significantly between the two groups, being lower in the group receiving a transfusion ($P<0{\cdot}05$).

Log rank analysis showed no significant difference between the time to recurrence ($P=0{\cdot}63$) or overall survival ($P=0{\cdot}57$) in the transfused and non-transfused patients. Regression analysis identified Dukes' classification ($P<0{\cdot}0001$) and depth of penetration ($P<0{\cdot}01$) as the only factors to have significant independent effects on time to recurrence. Blood transfusion had no independent effect ($P=0{\cdot}48$). For survival, the age and sex of the patient together with Dukes' classification and depth of penetration of the tumour had independent effects ($P<0{\cdot}01$). Again transfusion had no significant effect on survival ($P=0{\cdot}83$).

Subset analysis by site or timing of transfusion failed to demonstrate any adverse effect of transfusion on either time to recurrence or survival. A summary of the levels of significance is shown in *Table 1*.

Discussion

The reports of the beneficial effect of blood transfusion on renal allograft survival[1] prompted Gant to suggest that this effect may adversely affect patients with malignant disease[2]. Two retrospective clinical reviews have reported an effect of blood transfusion on both the time to recurrence and survival following resection of lung, breast and colorectal cancer[3,4]. In colorectal cancer, one study[3] has suggested that transfusion is second only to pathological stage as a prognostic indicator, while in others the tumour site[4] and operative transfusion were critical to identifying any effect.

The present study has failed to demonstrate any adverse effect of blood transfusion either on the time to recurrence or on survival and these have been shown to be independent of the time of transfusion and the site of the tumour. This concurs with the results from Nathanson *et al.*[5] who showed that transfusion had an adverse effect when considered in isolation. However, this effect was lost when a regression analysis was performed. Frankish *et al.*[7] have also failed to show an effect in a prospective study, which has a 3-year follow up.

It has been suggested that blood transfusion should be avoided in patients with malignant disease because of its adverse effect on survival The present study does not support this opinion.

Acknowledgements

We wish to express our thanks to Dr Mike Palmer for undertaking the statistical analysis in this study, to the surgeons in both regions for allowing us to study their patients and to the research nurses in both Birmingham and Manchester for their help and support in the running of this study.

Low molecular weight heparins and prevention of postoperative thrombosis

Sir

Two studies on the prevention of postoperative deep vein thrombosis (DVT) with low molecular weight heparin (LMWH) fractions have been published recently in *The British Journal of Surgery*. They deserve a few comments.

Although both trials claim superiority of the LMWH compound over standard heparin, 'intention to treat' analysis of the data reveals that this superiority is not statistically significant at the conventional P level of 0·05. In the Scandinavian study using Fragmin® (Kabi Vitrum, Stockholm, Sweden) (*Br J Surg* 1988, **75** 888–91), 28 isotopic DVTs (5·5 per cent) were detected in the LMWH group compared with 41 (8·3 per cent) in the standard heparin group ($P=0\cdot08$, two-sided test). The corresponding figures in the European Fraxiparin study (Sanofi Choay, France; *Br J Surg* 1988, **75** 1058–63) are 29 isotopic DVTs (3·0 per cent) in the LMWH group and 41 (4·4 per cent) in the standard heparin group ($P=0\cdot14$ two-sided Fischer exact test).

The analysis presented in the European Fraxiparin Study paper with correction of the isotopic DVT rate by integrating phlebographic data obtained in only 39 per cent of the cases with abnormal fibrinogen uptake test is not acceptable, especially because the study was not double-blind. Moreover, using a two-sided test, which is obviously more appropriate than the one-sided one when comparing two active treatments, reveals no significant difference between the two groups ($P=0\cdot065$), even with the corrected data. Thus, the two trials confirm and extend previous work showing that injection of a LMWH fraction once daily is at least as efficient as injection of standard heparin twice a day (Scandinavian study) or three times a day (European Fraxiparin Study) in general surgery. Bleeding complications also seem to be at least as frequent with LMWHs.

In the era of AIDS, these trials raise also the question of the safety of the fibrinogen uptake test as regards risk of virus transmission. In my opinion, injecting a blood derivative in asymptomatic patients for screening purposes should be seriously questioned. Possibly liquid crystal contact thermography which has a similar sensitivity and specificity in postoperative subjects[1] might represent an attractive alternative to the fibrinogen uptake test.

Authors' reply

Sir

The comments made by Dr Bounameaux are relevant and we are grateful to be able to answer.

We have given the data on intention to treat in our Results section in exactly the same way as Dr Bounameaux. In our protocol we made a biostatistical calculation to also be able to analyse patients who had been given correct prophylaxis as defined in the protocol. This is described in detail in the methodological section of our paper. Therefore we have given data both on the basis of intention to treat and on the basis of correctly treated patients. This is perfectly clear from our paper.

Dr Bounameaux has missed one important point in our study, which was new when we started it· the first dose given in the evening before surgery, which also contributes to the practicability.

Nowhere in our paper have we drawn any conclusion about a lower risk of bleeding with low molecular weight heparin. On the contrary, we stated, 'A disadvantage is the slight increase in haemorrhagic side effects, even though the bleeding episodes were of minor clinical importance.'

One important concern is the potential risk of virus transmission with fibrinogen used for diagnoses in the fibrinogen uptake test. When this risk became evident our study was stopped until the manufacturers could give a reasonable guarantee concerning their product, that is very few, reliable donors who repeatedly have negative HIV tests. Obviously a completely non-invasive test would be preferable but none exists today with the sensitivity of the fibrinogen uptake test. The suggestion of thermography based on the study by Pochaczevsky *et al*[1] seems less well founded as these authors compared phlebography and thermography in only 30 patients with suspicion of deep vein thrombosis. On the contrary, in postoperative patients the agreement with fibrinogen uptake test for screening was not as good and decreased when thrombi were localized distally[2]. With careful selection of fibrinogen donors this test remains the method of choice, at least in non-orthopaedic patients.

Author's reply

Sir

The letter of Dr Bounameaux deserves a few comments. The European Fraxiparin Study data were evaluated on the basis of intention to treat. Dr Bounameaux's statement that it would have been more appropriate to have used a two-sided rather than a one-sided statistical test to analyse the results is not obvious, especially since the form of analysis was chosen before the start of the study, and the number of patients probably required was based on this calculation.

The use of heated fibrinogen may minimize the risk of virus transmission using the fibrinogen uptake test. There are several reasons in favour of replacing this test, but none of the possible alternatives has been sufficiently tested so far.

Suction drains

Sir

Having read the article by A. Stacey-Clear and R. M. Hiddle (*Br J Surg* 1988, **75**. 1195), I would like to point out two faults with the method suggested by the authors for securing suction drains.

First, as the drain is not fixed at its point of exit, it is free to move in and out. This is more likely if the space or cavity being drained is large and there is sufficient length of drain between the tie and the point of exit. If the cavity is sterile, this movement from outside to inside is undesirable.

Second, as the tie passes through the drain and through the skin, it converts a closed system to an open one.

With good surgical technique using a strong braided suture and careful nursing, there is no reason why a drain, secured in the traditional way, should fall out.

Endoscopic sphincterotomy

Authors' reply

Sir

We were interested to read the letter from Messrs Bickerstaff, Chapman and Britton (*Br J Surg* 1989; **76**: 316) and their criticism that we had not referred to the four papers that they quote. In fact we did refer to the previously published paper in the *The British Journal of Surgery*[1]. We were also aware of the other three papers but did not feel that two[2,3] were worthy of discussion as they were reports of very small numbers of patients (five and 16, respectively).

In such small series it is not surprising that the authors were able to report 100 per cent success and no complications or deaths, results unlikely to be borne out by greater experience. We were also aware of the fourth paper they mentioned[4] but found ourselves in some difficulty interpreting the results. This paper is not confined to endoscopic sphincterotomy for retained bile duct stones and within it there are certain discrepancies. It is stated that 76 patients underwent this procedure, but later the authors refer only to 75 patients, claiming successful clearance of the duct in 72 (96 per cent). They state that there were no complications but mention without qualification that in one patient, a basket broke in the bile duct. We are not informed what happened to this patient or to the two patients in whom the stones could not be extracted

We emphasize that we have reported a 30-day mortality rate but it is not apparent whether this was so in the papers quoted One of our patients died following surgery for an impacted basket and another following surgery for unsuccessful endoscopic clearance of the bile duct Our complication rate was 12 per cent if occult haemorrhages are excluded (not 15 per cent as suggested). We remain cautious about endoscopic removal if other alternatives which are less hazardous but equally successful are available.

The early recourse to endoscopic retrograde cholangiopancreatography and sphincterotomy proposed by Bickerstaff *et al.* is surely premature; many patients with small stones retained after exploration will pass their stones spontaneously if left without interference We consider it unwise to perform early, possibly unnecessary, endoscopic sphincterotomy simply to allow removal of the T tube.

In view of the last sentence in their letter we should like to point out that it was exactly the philosophy that it might be safer to leave stones behind for later endoscopic removal that was adopted in the morbidly obese 43-year-old man with cholangitis and jaundice, and ultimately an impacted basket, who died.

Rectus abdominis muscle flap

Sir

We read with interest the recent report by Young *et al.* (*Br J Surg* 1988; **75**. 1228) We have recently used a rectus abdominis muscle flap to try to heal a persistent perineal sinus, but have met with limited success.

A 31-year-old man presented with a perineal sinus following panproctocolectomy for longstanding ulcerative colitis. The sinus, present for 2 years, was associated with low back pain, a variable urinary system and difficulty gaining and maintaining full erection Occasionally small bowel contents were thought to be discharged At a subsequent laparotomy, left psoas and pelvic abscesses were drained and a small bowel fistula divided from the pelvic diaphragm and repaired.

One year later, the perineal sinus/fistula recurred, together with left loin pain, ill health and weight loss. At laparotomy, a large left loin abscess was drained and a rectus abdominis muscle flap based on the inferior epigastric pedicle was transposed to lie in the pelvis A pelvic suction drain was used and the anterior abdominal wall was closed with polydiaxonone sutures No attempt was made to repair the posterior rectus sheath and the deformity is negligible

One month postoperatively, the perineal wound continued to discharge. Six months later, bilateral gracilis muscle flaps were transposed to the posterior pelvic cavity, resulting in perineal healing. Suction drainage was again used in the early postoperative period. There has been no recurrence of the sinus in the 6 months since the operation The patient's urinary system and sexual function have returned to normal and there has been no loss of function secondary to the use of these three muscle flaps

This case suggests that the rectus abdominis flap was successful in controlling the fistulation tendency and probably filled the upper part of the cavity. This left a space which was well managed by the standard gracilis transposition procedure, which offers a useful additional flap(s) with little or no postoperative morbidity The use of suction drainage of the muscle flaps and pelvis as described in the case report would seem to be important.

Endoscopic treatment of acute biliary pancreatitis

Sir

Mr Neoptolemos and his colleagues have clearly demonstrated that the systemic use of urgent endoscopic retrograde cholangiopancreatography (ERCP) during attacks of acute pancreatitis is a valuable method for the detection of common bile duct stones (*Br J Surg* 1988, **75**: 954–60) If stones are found, endoscopic sphincterotomy should be performed. Neoptolemos *et al.* reported a 19 per cent overall complication rate and a 2 per cent mortality rate of this technique in gallstone pancreatitis

Endoscopic sphincterotomy is not generally accepted as the first method in the treatment of acute biliary pancreatitis. It is therefore of interest to evaluate the efficacy of endoscopic sphincterotomy in acute pancreatitis due to gallstones. This was done by an international survey of the procedures performed in 19 middle-European endoscopic departments[1]

In this collected series, out of 11 830 endoscopic sphincterotomies, 261 (2·2 per cent) were performed in patients with acute biliary pancreatitis All of the sphincterotomies were done within 48 h The bile duct stones were shown during endoscopic retrograde cholangiography.

The endoscopic procedure was successful in 236 (90·4 per cent) cases out of the 261 patients. Complications developed in 13 patients (5·5 per cent) haemorrhage in eight patients, pancreatic necrosis in four cases and sepsis from biliary origin in one patient. Surgery was needed in four cases.

The mortality rate was 1·9 per cent The cause of death was pancreatic necrosis in four cases and biliary sepsis in one patient

The results of our international survey show that endoscopic sphincterotomy is a safe procedure in the treatment of acute pancreatitis due to gallstones.

The participants of the survey were: Austria, P. Kratochvil, W. Weiss; Czechoslovakia, S. Safar, A. Vavrecka, GDR, R. Arendt, H Bosseckert, K.U. Schentke, E Schwenke, D. Wöstenberg, Hungary, Z. Definitive one-stage emergency large bowel surgery

Sir

Mr Mealy and his colleagues (*Br J Surg* 1988; **75**. 1216–19) decided, in electing to treat obstruction and perforation of the large bowel by immediate resection of the diseased segment, that they would also 'avoid a colostomy except for compelling reasons' While welcoming their report, we would like to comment on their conclusions

There is now a considerable measure of agreement on the management of neoplastic large bowel obstruction. Right hemicolectomy is now the standard treatment for obstruction in the proximal colon, and, increasingly, extended right hemicolectomy[1] with immediate ileocolic anastomosis is used for neoplasms in and just beyond the splenic flexure; a stoma is hardly ever needed. With increasing use of intraoperative colonic emptying it is possible to carry out immediate resection and a safe restorative anastomosis on lesions obstructing the left colon, and here our policy[2] and that of Mealy and his colleagues appears to be similar. They performed primary anastomosis in 25 of 31 patients (81 per cent) with a left colon obstruction, compared with our figure of 47 anastomoses in 52 patients (90 per cent) In both series the mortality rate was around 10 per cent, most deaths being due to intercurrent disease

However, caution must be exercised in suggesting so definitely that this type of surgery can be carried out by registrars – a term which embraces trainees with widely differing degrees of experience. The most careful judgement must be exercised when deciding whether these elderly and often unfit patients will benefit from an operation which takes longer and can carry a higher risk, and the operator must already have considerable experience of elective colonic resection. The large series from the Large Bowel Cancer Project[3] is not reassuring about the results achieved by registrars in this field, and the CEPOD report[4] is a reminder of the lack of supervision which can prevail. In this field, everything depends on the expertise and advice available at the time of operation.

We have serious misgivings about the promotion of a deliberate policy to avoid a stoma when treating colorectal perforations. In assessing such a policy it is important to be careful about the use of the term 'peritonitis'. *Table 2*, which analyses 'pathological grade of peritonitis' in 68 patients undergoing laparotomy, shows that 36 (53 per cent) had localized inflammation without pus in the peritoneal cavity. In some of these patients it might have resolved under conservative management[5], and certainly it would be wrong to draw any conclusion about the safety of anastomosis in the presence of peritonitis from the results in this group. Sixteen of 26 patients with generalized peritonitis had a resection with anastomosis, but the outcome is not known. In the 36 patients in our study[2] who had a primary resection for colonic perforation with purulent of faecal peritonitis, only 12 had an anastomosis as it was thought safer to make an end stoma in 24: there were two deaths (5·5 per cent). Ryan[6] was a keen advocate of resection and anastomosis for perforated sigmoid diverticulitis, but he only used this method in half his patients, and advised caution in the presence of diffuse peritonitis.

Although there is a strong surgical tradition that there is a greater risk if a colonic anastomosis is made in the presence of peritonitis, there is no firm clinical evidence to support this belief. However, there are two good reasons for exercising caution. One is that these patients are often already toxic and ill, and may not be well served by an operation taking an extra 45–60 min. The other reason is that there are very few reports of emergency anastomosis of the colon without the occurrence of some subsequent leaks from the suture line (overall incidence was 8·4 per cent in the series of Mealy *et al*, and 6·6 per cent in ours). It is doubly unfortunate if this complication occurs in a patient who is already suffering from diffuse peritonitis, even though it may be resolving.

We believe, therefore, that it is most unwise to state in the summary, without qualification, that 'resection and primary anastomosis can be performed with acceptable morbidity and mortality in a high proportion of large bowel conditions, irrespective of ... the presence of peritonitis'.

Authors' reply

Sir

We appreciate the interest and comments of Professor Jones and colleagues from Aberdeen on our paper.

We fully support the contention that emergency large bowel surgery is exacting and requires good judgement and operative experience. Furthermore, we did note the recent CEPOD report and acknowledge that close co-operation between registrars and their consultant colleagues is essential.

The decision to operate or to manage conservatively localized inflammation of the colon is difficult. We agree that little can be inferred from the results of primary anastomosis in this group. For this reason we carefully defined the degree of peritonitis in a similar manner to that previously reported by the Aberdeen group. One death occurred in our group of 16 patients with generalized peritonitis who underwent a resection and primary anastomosis (6·25 per cent). This was due to multiple organ failure in a 54-year-old woman with lymphomatous perforation of her sigmoid colon. Of interest is the fact that one of four patients with generalized peritonitis who had a Hartmann procedure also died.

We also agree that caution is required in performing a primary anastomosis in these groups of patients. However, we believe that in many cases it takes little longer to perform a left colonic resection and anastomosis than to perform a Hartmann procedure, most now accept the need to resect the inflammatory lesion at initial operation. We re-emphasize that our intraoperative colonic evacuation takes approximately 10 min.

We feel that our conclusions were qualified and are justified by demonstrating that a high proportion of large bowel conditions can be managed in this fashion.

Acute lower limb ischaemia

Sir

We read with interest the recent paper by Walker and Giddings (*Br J Surg* 1988; **75**: 1189–92) on the treatment of acute lower limb ischaemia using intra-arterial streptokinase. They suggest that this treatment is particularly useful in three situations, namely, acutely thrombosed popliteal aneurysms with tibial artery thrombosis, thrombosis of an autogenous vein graft and embolization of a cardiac thrombus following acute myocardial infarction. Streptokinase may also be of value in patients with non-acute ischaemia, as relatively fresh thrombus may be found within an atheromatous occlusion.

We have treated 11 consecutive patients with chronic lower limb ischaemia due to arterial occlusions apparently not suitable for either vascular reconstruction or angioplasty. Seven patients had rest pain, and four had incapacitating intermittent claudication of more than 1 month's duration. We used a technique similar to that of Walker and Giddings but with a higher dose of streptokinase (20 000 units/h) for between 18 and 72 h. In four patients the vessel was cleared sufficiently to allow successful angioplasty, with clinical, radiological and Doppler pressure improvement. One patient had considerable dissolution of thrombus, but angioplasty was still not possible. One patient subsequently underwent femoropopliteal bypass grafting, having had no objective improvement from streptokinase, only one patient required an amputation. All but the last patient had some subjective benefit. Three patients developed haematomas, the streptokinase infusion being terminated in one and temporarily discontinued in another. In one patient there was slight derangement of clotting (INR 1·8).

Streptokinase is clearly less effective in chronic compared with either acute or subacute ischaemia. Nevertheless, we feel that for those patients with severe symptoms who are not suitable for either reconstruction or angioplasty, intra-arterial streptokinase should be considered as even partial clearance of the vessel may permit subsequent successful intervention.

Lower gastrointestinal bleeding

Letter 1

Sir

In his leading article 'Lower gastrointestinal bleeding', Mr Spencer (*Br J Surg* 1989; **76**: 3–4) failed to mention the technique of intraoperative colonoscopy with antegrade colonic irrigation[1]. We believe this procedure to be an important recent development in the diagnosis and treatment of major colonic haemorrhage. Although mesenteric angiography and radioisotope scanning can undoubtedly be helpful in moderate or intermittent bleeding, they have little place in the management of major colonic haemorrhage, may cause a dangerous delay to urgent surgery, and are less likely to reveal the precise site of bleeding than intraoperative colonoscopy[2].

It is disturbing to read in 1989 that blind colonic resection, subtotal colectomy and the formation of a transverse colostomy should still be advocated. In an extensive review of the literature[3] we found that blind colectomy in patients with major active lower gastrointestinal bleeding was associated with an unacceptable rebleeding rate of approximately 30 per cent and a mortality of 20–40 per cent. Accurate localization of the site of haemorrhage allows an appropriate limited resection and should be the aim of the surgeon when treating patients with life-threatening haemorrhage. This can and should be achieved by early operation and intraoperative colonoscopy with antegrade colonic irrigation.

Lower gastroinestinal bleeding
Letter 2

Sir

While agreeing with much of Mr Spencer's review of lower gastrointestinal haemorrhage (*Br J Surg* 1989, **76**: 3–4), we were disappointed that there was no mention of localizing bleeding by isotopic methods. The advent of *in vivo* labelling of red blood cells with technetium-99m has provided a simple yet elegant investigation[1] which should be considered as well as arteriography and colonoscopy. The main disadvantage of angiography is that there must be active bleeding at the time of contrast injection for the investigation to succeed. Scintigraphic detection of bleeding does not have this limitation because extravasated radiolabelled red blood cells accumulate at a bleeding site and can be detected by scanning which may be delayed by up to 36 h after the injection of isotope. This feature, along with the ability of scintigraphy to detect lower bleeding rates (0.05–0.1 ml/min)[2] than angiography (0.5–1.0 ml/min)[3], make it particularly suitable for the investigation of lesions which bleed slowly and intermittently.

Over a 3-year period we have performed 43 isotope scans in 41 patients with lower gastrointestinal haemorrhage, the investigation proving to have a sensitivity of 97 per cent and a specificity of 85 per cent[4]. We found that the investigation was particularly useful in localizing the bleeding point to either one side or the other of the colon in cases of angiodysplasia and diverticular disease. Of the 12 large bowel resections performed only one was a subtotal colectomy.

Red cell scanning will not provide all the answers in cases of lower gastrointestinal bleeding but our experience suggests that it deserves further study and more widespread use.

Organ donation

Sir

The paper by Wakeford and Stepney (*Br J Surg* 1989, **76**: 435–439) is a commendable attempt to identify the obstacles to organ donation by surveying the attitudes of the general public and the medical and nursing professions. Unfortunately, they have failed to identify any obstacles and in consequence their recommendations for increased training of staff and education of the public are bland, unsupported by their own evidence, and almost certainly useless.

Intensive care unit staff were invited to indicate which of nine factors they saw as restricting organ harvesting in their own units. None were thought to be definitely important by even a quarter of those responding. Why then are more donors not being referred? Lack of training in how to approach relatives was thought definitely to be a factor by only 4 per cent of the doctors whose task it should be to make such approaches. Education and advice on transplantation would apparently be valued by only 25 per cent of the general public while 35 per cent expressed antipathy to the suggestion. It would be remarkable if training of those who see no need for it and education of those who do not want it achieved the desired aim of increasing the supply of organs for transplantation.

If organ supply is to be improved we need to know why all suitable donors are not being offered to transplant teams at present. Three questions which the authors could have asked intensive care unit staff might have provided interesting answers.

1. How many potential organ donors have you treated in the last year?
2. How many were referred for organ donation?
3. What were the reasons for non-referral in each case?

If truthful answers were given we could at least discover the reasons why so many usable organs are currently wasted. We need to know the real answers to these questions so that effective recommendations can be made to increase the present inadequate supply of organs for donation.

Partial fundoplication after abdominal Heller's myotomy

Sir

The publication by Crookes *et al* (*Br J Surg* 1989, **76**. 99–100) advocating partial fundoplication after abdominal Heller's myotomy is critical of previous published work and in particular of a recent collective review[1] which concluded that a higher incidence of reflux is encountered after myotomy performed through the abdomen as opposed to the thoracic procedure. The data accrued from retrospective series on the short thoracic myotomy which does not extend beyond 1 cm into the stomach and which takes care to avoid disruption of the gastro-oesophageal fixation would support the view that this procedure is followed by an incidence of reflux which is half that following abdominal myotomy. This argument and the persistent controversy are circuitous since the data on which they are based are totally uncontrolled.

There is an ongoing study on achalasia in this department. To date, 18 patients have been studied by 24-h pH monitoring, manometry and oesophageal isotope transit before and after myotomy. Insofar as the reflux status is concerned, three patients demonstrated pathological acid reflux before myotomy and 15 did not. The latter group were treated by a short thoracic myotomy, and postoperative testing at 3–6 months showed no reflux. Thus it would seem that some patients have reflux preoperatively and would need an anti-reflux procedure whether the myotomy is carried out through the chest or the abdomen. The majority, one suspects, do not require this added procedure if the myotomy is performed through the chest. Perhaps more widespread preoperative testing for reflux would solve the controversy and allow rational patient selection. In the absence of hard evidence, one could postulate that the abdominal operation is more likely to disrupt gastro-oesophageal fixation and precipitate reflux. If an anti-reflux operation is considered advisable, it is indeed sensible to advocate an incomplete wrap since this is less likely to cause oesophageal emptying problems in view of the aperistaltic characteristic of this disorder.

Finally, in the interest of accuracy, Messrs Crookes *et al* should perhaps acknowledge that the operation they describe was reported several years ago by Toupet[2] and subsequently popularized by Boutelier and Jonsell[3]. For my part, I have found this operation superior to the complete wrap for the treatment of reflux disease and now use it routinely to treat this disorder.

Book reviews

A Colour Atlas of Surgical Management of Venous Disease

C V Ruckley. 308 × 254 mm. Pp 128. Illustrated. 1988. London Wolfe. £35.00

One of the perks of reviewing books is that you are usually rewarded by being allowed to keep the book Sometimes this is a dubious pleasure, but I am delighted to be able to place this highly illustrated and beautifully produced monograph on my shelves. Having recently produced a venous textbook, I am extremely envious of the superb colour operative pictures that Vaughan Ruckley and Wolfe Medical have used to illustrate this atlas. The book is primarily an operative manual, although it does contain sections on venous anatomy, assessment, sclerotherapy and compression therapy There are one or two technical points with which I would disagree, particularly the suggestion that the long saphenous vein should be divided before the saphenofemoral junction has been identified (even though the author stresses 'provided there is no doubt as to its identity') These apart, and all surgeons have their own operative idiosyncrasies, it is an excellent little book which should appeal to both the novice and the experienced surgeon alike I will encourage all our new Senior House Officers to read it before they start operating on patients with varicose veins and venous ulcers.

Microsurgery in Trauma

W. D Shaw and D A Hidalga. 216 × 279 mm Pp 396. Illustrated. 1987. New York, Futura Print Company $87 50.

Trauma is the leading cause of death among young adults, and is the commonest cause of permanent disability within the population The psychological, social and economic consequences of trauma demand the surgical skills of reconstruction and salvage to preserve function and appearance. Microsurgery has added a new dimension to this field, re-defining the rules of management, and encouraging early definitive and comprehensive reconstruction

This text is based on the experience of a single skilled plastic surgical department, well versed in the application of microsurgery in trauma The work is divided into four sections. the basic principles, replantation, nerve injuries and tissue transplantation

The first section contains useful information on the microscope and microinstruments, and provides a clear description of microsurgical techniques and methods for monitoring reconstructions

The section on replantation emphasizes the pathophysiological consequences of amputation and ischaemia. The mechanisms of injury are linked to defining the best possible goals, surgical management and subsequent outcome. Upper limb replantation is given more emphasis than lower, although the motivation to walk may be higher than to return to manual work, lower limb prostheses are well developed and well tolerated Secondary lower limb reconstructive procedures and salvage, however, have an important role

The section on nerve repair concentrates primarily on upper limb injuries Repair of avulsion of the roots of the brachial plexus is biologically and technically futile However, myelography is in itself not diagnostic of this condition and the authors consider that other diagnostic modalities, in particular surgical exploration, should also be undertaken

The largest section of the book is on tissue replantation Replantation techniques mean that the tissue available for reconstruction is not restricted to the local vicinity of an injury The wide variety of flaps, containing not only skin, but also muscles, tendons, vessels and nerves, provide unique characteristics appropriate to local needs The historical basis, surgical anatomy, flap design and flap dissection are considered for each donor site and a full bibliography supplied

The whole text provides a clearly written comprehensive cover of the chosen topic Detailed anatomy and practical procedures are discussed at a level that is not collectively available elsewhere The diagrams reflect the dual artistic and surgical background of the second author, and represent a unique guide to reconstructive procedures. The black-and-white photographs are not of equivalent quality, but do not detract from the overall value of the work

Management of these problems requires a skilled and well-organized team, with senior continuity Enough team members are required to ensure expert emergency and subsequent management, the optimal choice and undertaking of reconstructive procedures, and comprehensive postoperative care, rehabilitation and follow-up. The authors have succeeded in providing an excellent guide to these contemporary requirements for microsurgical reconstruction in trauma

Reducing Traffic Injury—A Global Challenge

G W. Trinca, I R. Johnston, B. J Campbell et al. *178 × 254 mm. Pp 112 1988. Melbourne A. H. Massina £13 00*

This short monograph is powerful stuff! It should be compulsory reading for those in the higher echelons of government and the medical and legal professions It has been written by seven individuals from Australia, Canada, the UK and the USA, all of whom have interest and expertise in road traffic injuries. They have come together under the umbrella of the National Road Trauma Committee of the Australasian College of Surgeons The Australasian College already has a fine record in the field of prevention of injury, having been largely responsible for the production of evidence about the efficacy of seat belts. It is good to see them continuing to forge ahead in this field Under the Chairmanship of Dr G. W Trinca, a Melbourne General Surgeon with a major interest in the prevention and management of road traffic injury, the authors have produced a compelling statement of the current and forthcoming problems and possible solutions.

The message is stark but simple In the world today, 15 million people are injured each year in road traffic accidents and half a million die By the turn of the century these numbers will double.

The seven chapters in this book cover the present situation, and they provide a forecast of the problems posed by rapidly increasing traffic throughout the world, a view of the role of institutions in dealing with the problems and a chapter on strategies to reduce injury One can tell this book has been written under the supervision of a surgeon The style is terse and hard-hitting Words are not wasted The problems are clearly stated and the recommendations are set out in short statements to give maximum impact

Much of what is written is directed at governments and major institutions such as the World Health Organization, the Organization for Economic Co-operation and Development and the World Bank However, there is advice for those whose task it is to manage the injured It is noteworthy, in view of the present debate taking place in this country, that the authors come down firmly in favour of an integrated trauma service with trauma centres for the treatment of the most severely injured

This book helps to restore the balance in terms of priorities in medical matters Perhaps cancer and heart disease, primarily conditions of the old and retired, have held the foreground for too long. It is time that injury, the principal cause of death in the young and economically active section of the community, was placed first on the agenda

This book will help to do this. It is mandatory reading for all interested in the prevention, as well as the management, of surgical disease

SPECIALTY EXAMINATION IN UROLOGY

Royal College of Surgeons of Edinburgh
Royal College of Surgeons of England
Royal College of Physicians and Surgeons of Glasgow
Royal College of Surgeons in Ireland

The next Intercollegiate Specialty Examination in Urology will be held in the London Hospital, Whitechapel, London, on Friday, 22 September 1989.

Candidates will be required to hold the Surgical Fellowship of one of the Royal Colleges of Surgeons of Great Britain or Ireland and to have completed a period of post-Fellowship training in posts approved by the Intercollegiate Board in Urology of not less than four years, as follows:

(a) one year in General Surgery in posts approved by the Joint Committee on Higher Surgical Training;
(b) three years in Clinical Urology in posts approved by the Specialist Advisory Committee in Urology. At least one year of this period must be at the Senior Registrar level.

The Regulations and application form may be obtained from the Secretariat, Intercollegiate Specialty Boards, 10 Hill Square, Edinburgh EH8 9DR.

Completed applications for entry must be received by Friday, 4 August 1989.

Fee: £230

WORLD ASSOCIATION OF HPB SURGERY

3rd World Congress on Hepato-Pancreato-Biliary Surgery

3-8 June 1990
Royal Borough of Kensington and Chelsea
Town Hall, London, UK

The Scientific Programme will be devoted to all major topics of HPB Surgery and will comprise keynote addresses, free paper, video and poster sessions and panel discussions. Keynote addresses will be given by:

Nancy Ascher – Liver Transplantation
Henri Bismuth – Portal Hypertension
John Cameron – Cholangiocarcinoma
David Carter – Pancreatitis
Arthur Li – Primary Liver Tumours
Miles Little – HPB Trauma
Dame Sheila Sherlock – Hepatitis
Michael Trede – Carcinoma of the Pancreas

Brain Imaging – An Introduction

John R. Bradshaw BA MB BCh DMRD FRCR FRCP(C)
Consultant Neuroradiologist, Frenchay Hospital, Bristol

- ★ Illustrates the many diverse manifestations of brain disease
- ★ Describes the best use of current imaging techniques in diagnosis
- ★ 100 case presentations, invaluable for self-assessment

As the range of possible techniques for brain diagnosis widens, the need for guidance as to which technique is most appropriate for a given problem has never been more acute. It is the purpose of this book to fill this need, and to illustrate the diverse manifestations of brain disease as revealed by these techniques.

Contents: Part 1 – The techniques Plain skull radiographs • Plain-film tomography • Radionuclide (isotope) brain scanning • Cerebral ultrasound • Cerebral angiography • Computerized axial tomography (CT) • Magnetic resonance imaging (MRI) **Part II – The cases** Subacute or recurrent headache • Acute headache • Sudden unilateral weakness • Unilateral weakness of gradual onset • Speech disorders • Seizures • Pituitary and parasellar lesions • Coma • Sensory disorders • Posterior fossa and cranial nerves • Dementia and psychotic states • Congenital lesions • Suggested further reading • Pathology Index • Index

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications.* New York: Springer-Verlag 1981: 123–63.

Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality.

Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range.

Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp–that's why they are World-Famous!

British Council International Specialist Medical Course

Strategies in the management of acute trauma

24–29 September 1989, Belfast

This course is designed to review the recent advances and current concepts of acute trauma management. It will include lectures, workshops, case presentations, interactive discussion groups and hospital visits.

Major topics for review will include: pathophysiology of trauma; prehospital care of the trauma victim, immediate hospital care; review of injury management; intensive care management; management of complications; disaster management and rehabilitation of the injured.

The Director of Studies will be Professor Brian J Rowlands who, prior to coming to Belfast in 1986, had 9 years' experience working in a category I Trauma Centre in Houston Texas, USA and is a fellow of the American Association for the Surgery of Trauma.

The course is designed for surgeons who are actively involved in the management of severely injured patients and should be of Consultant or Senior Registrar status.

There are vacancies for 30 participants.

Fee: £815 includes academic programme, accommodation and all meals.

Working sessions will be held at Postgraduate Medical Centre at the Belfast City Hospital. Participants will be accommodated at a comfortable, modern hotel.

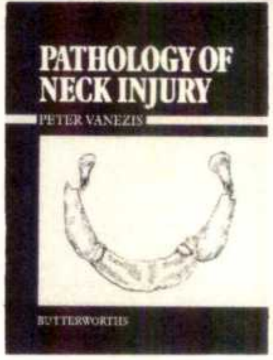
The British Council

Further information and application forms are available from British Council Representatives overseas or from Courses Department, The British Council, 65 Davies Street, London W1Y 2AA.

NEW FROM BUTTERWORTHS . . .

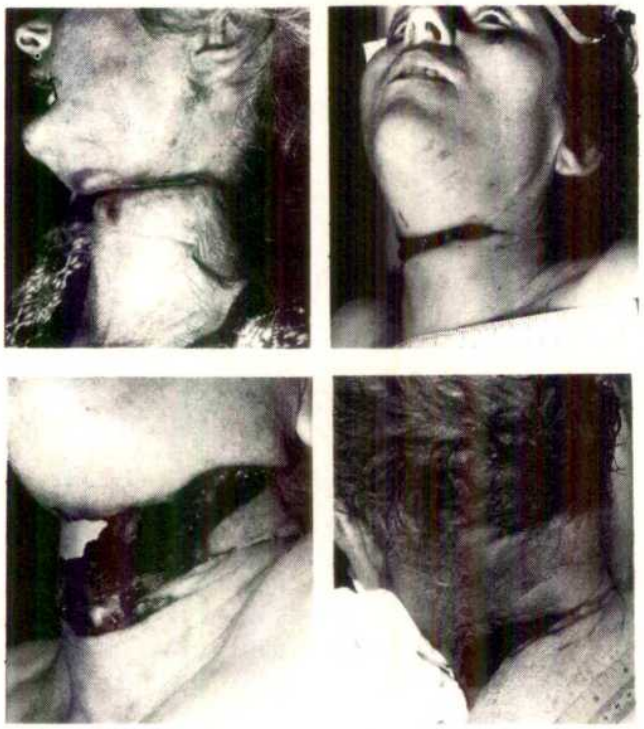
Pathology of Neck Injury

Peter Vanezis, MD, MRCPath, DMJ(Path)
Senior Lecturer in Forensic Medicine, Department of Forensic Medicine, The London Hospital Medical School, UK.



- **a practical guide and general reference dealing with all pathological aspects of neck injury**
- **of interest to everyone engaged in forensic work as well as pathologists and ENT surgeons**
- **covers all aspects of injury in the neck region including the airways, trachea and larynx etc.**

In the clear and highly illustrated text, Peter Vanezis first explains the anatomy of the neck region and the various techniques required in its examination. He then describes penetrating injuries, comprising mainly sharp force trauma and firearm injuries. Asphyxial and related deaths are subsequently discussed in a series of five chapters before the author turns to the examination of blunt impact (non-compressive) injuries, and here special reference is made to their common occurrence in road traffic accidents. Finally, Dr Vanezis concerns himself with environmental, toxic and iatrogenic causes of injury.



Where appropriate, and especially with regard to penetrating and compressive modes of trauma, the interpretation of injuries and their differentiation into various categories such as homicidal, accidental or suicidal has been emphasized.

Pathology of Neck Injury is an essential guide for all those involved in the relevant specialties of pathology, surgery and forensic medicine.

Contents Introduction · Anatomy · Techniques of examination · Penetrating injuries · Compressive neck injury: I – Signs of mechanical asphyxia, II – Manual strangulation, III – Ligature strangulation, IV – Hanging · Internal airway obstruction · Non-compressive blunt impact injuries to the anterior compartment · Non-compressive blunt impact injuries to the posterior compartment · Toxic and miscellaneous environmental causes of neck injury · Injuries resulting from therapeutic, investigative and other related actions · Index

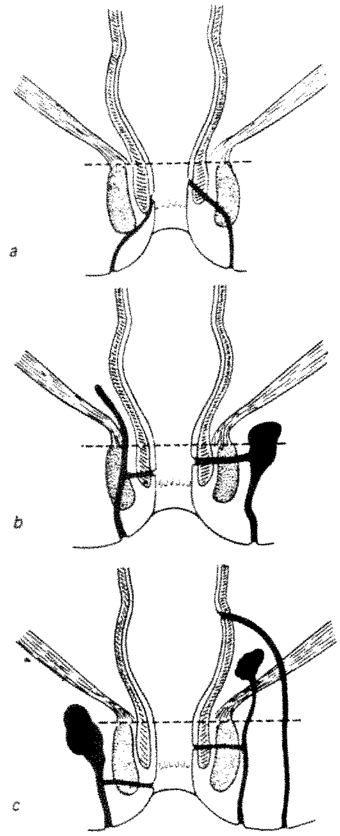
Essential Surgical Practice
Second Edition
Wright



★ Second edition of this classic systematic and comprehensive surgical textbook ★ Thoroughly revised and completely up-to-date ★ The section on cardiac surgery has been rewritten and to reflect its increasing importance there is a completely new section on trauma surgery ★ Over 100 new illustrations ★ Comprehensively indexed ★ Many references for further reading

Reviews

'What differentiates this textbook of surgery from many others is the clarity and simplicity of the text, the very liberal use of complementary tables, the illuminating simple diagrams, and the book's clinical relevance. The ease with which it may be read and the subject material understood makes this book a superior choice for students and residents interested in learning the essentials of surgical practice.'
The New England Journal of Medicine

'This book is highly readable and is a real contribution to surgical education.' *Archives of Surgery*

'It should be a great success on both sides of the Atlantic.' *Annals of the Royal College of Surgeons*

'. . . Covers very well an extensive range of material which is well illustrated and readily comprehensive. It should be very useful equipment for the trainee surgeon for the Australasian college.'
New Zealand Medical Journal

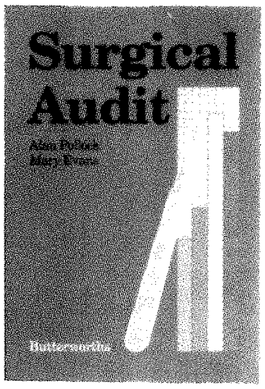
Surgical Audit

Alan Pollock BSc FRCS FRCS(Ed)
Consultant Surgeon, Department of Surgery,
Scarborough Hospital, Scarborough, UK

Mary Evans BA
Research Co-ordinator, Department of Surgery,
Scarborough Hospital, Scarborough, UK

- ★ **written by acknowledged experts in the field**
- ★ **essential reading for all surgeons with the increasing demands for quality control, patient satisfaction and cost effectiveness**
- ★ **enables surgeons to set up and evaluate their own audit systems**

This book provides practical advice on how surgeons can evaluate the various facets of surgical practice and their effective management.



Surgical Audit will be an essential book for all practising and trainee surgeons and will be welcomed by hospital administrators and all those involved in the day-to-day running of surgery departments.

Contents: The history of audit • The evolution of surgical audit • What is audit? • Economic audit introduction • Economic audit: reducing hospital stay • Diagnosis related groups and performance indicators • The containment of costs in surgery • The containment of costs of health care in the USA • Recording, retrieval and analysis of clinical data • Introduction to audit of outcome • An example from the SENIC program • Random control trials • Confidential enquiry into perioperative deaths • Quality of life after surgery • Mishap and malpractice • Measures to encourage professional competence • Introduction to audit of patient satisfaction • Waiting for hospital treatment • The sanctity of life • Clinical surgery • Human experimentation • Peer review of papers submitted to scientific journals • Audit of surgical publications • The presentation of audit of outcome • Index

Br. J. Surg. 1989, Vol. 76, June, 531–532

Extending surgical audit: the assessment of postoperative outcome

Everyone involved in health care is subjected increasingly to greater accountability. The present Government's concept of 'value for money' seems destined to be applied more and more to the Health Service; a policy that will inevitably involve auditing not only resources but results. If surgeons are to 'sell' their skills on an internal National Health Service market, what criteria will be used to judge which hospital or firm or consultant is best for a particular referral? In many instances personality or geographical proximity will remain the major determinants. In other cases general practitioners and their patients may be guided more by proven results. Surgical audit seems destined to increase.

Auditing of process is already with us in the form of performance indicators of workload such as numbers of new out-patients, admissions and operations, and these are now applied to most surgeons in the UK. Yet the present emphasis on resources and their management has diverted attention from the aspect of more concern to doctors and patients – the outcome of surgical treatment. There is little merit in a clinician topping a league table for operations performed if these are inappropriate or the results are bad.

The case for surgical audit is now well established. Audit has advantages across the spectrum of those involved in patient care. It can tell surgeons how their results compare with those of their peers – an important contributor to job satisfaction perhaps, or a stimulus to improved technique. It can tell both surgeons and managers whether better performance indicators and lower costs are achieved at the expense of, for example, increased re-admission and complication rates. In short it can tell us all whether we are achieving our aims in surgical care.

Surgeons, especially gastrointestinal surgeons, were pioneers of auditing long-term outcome in their patients. Billroth was not only the father of gastrointestinal surgery but was the originator of surgical audit. In the UK, Tanner[1] and Visick[2] demonstrated both the feasibility and the value of long-term follow-up after peptic ulcer operations. These and a few others like them established exhaustive and detailed follow-up after gastric surgery and with them began reliable follow-up where only clinical impression had gone before. For example, in 1928 the largest prospective study then published, involving some 744 patients, reckoned the recurrent ulcer rate after gastroenterostomy at 2·8 per cent[3]. Even centres of excellence were not immune from dubious results; the recurrence rate at the Mayo Clinic was claimed to be 3·5 per cent after a minimum follow-up of 5 years[4]. These results we now know reflect inadequacy of follow-up rather than operative success. Has the audit of surgical outcome improved 60 years on?

Individual surgeons do not have the resources to follow up all cases in the long term. It is difficult enough for most surgeons to follow up those groups of patients in whom they have a particular interest. Pressure on hospital resources has squeezed out-patient clinics, making increasingly inappropriate the continued review of patients who remain well years after long-forgotten operations. How, then, can individual surgeons know whether their results compare with those published in the literature? How can individual surgeons know, for example: whether their recurrence rate after surgery for duodenal ulcer is 5 per cent or 40 per cent; whether their 5-year survival rate after resection for colorectal cancer is 40 per cent or 70 per cent; what the symptomatic results of their transurethral resections are after more than 1 year (how many of their patients are incontinent and how many require a further resection); whether their palliative resections for gastric cancer improve the quality of life or whether the patient is better off without surgery? It is unlikely that these questions can be answered by follow-up at the routine out-patient clinic without a structured document for collecting the data. Most surgical clinics are too busy to allow this additional time-consuming chore. It is equally unlikely that surgeons would take time to analyse such documents manually. If an audit system is to succeed it must involve minimal extra work for clinicians and secretarial or clerical staff; it must be cheap and easy to use; and it must provide relevant results which are wanted by the clinician.

The origins and working of our Surgical Review Office formed a logical, natural progression from a gastric follow-up clinic. The decline in incidence of peptic ulcer since the 1960s and the even more dramatic decline in its surgery in the 1980s necessitated diversification into other areas. Our system now audits operations for peptic ulcer (elective and emergency), gastric cancer, gastro-oesophageal reflux and colorectal cancer. The detailed techniques of recruitment, documentation and follow-up have been described elsewhere[5].

Who should do the audit? Registrars and research fellows are employed on a short-term basis. As a result, short-term follow-up studies abound, as do 'snapshot' studies of the last 50 '-ectomies' or '-plasties'. But to obtain a sustained long-term audit of a consultant's results requires that the consultant should make time to do it personally. Only the consultant has the

0007-1323/89/060531-02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

continuity of employment to sustain the continuing organization of a long-term audit system.

Whilst enthusiasts have and will continue to audit their results for self-assessment, others remain to be convinced. There are some who believe that if our political and managerial masters wish to know the results of our clinical endeavours it is they and not we who should do the auditing. This option, which would involve employing medically qualified 'assessors' working for the manager, is an option that would be much less attractive to most clinicians and unacceptable to many.

Deciding which groups of patients to study in a consultant's or firm's practice and what information to collect about them involves little time and no financial outlay. The powerful commercial database packages now widely available for modern microcomputers make design of the collecting documents easy – the days of elaborate codes and margins full of numbered boxes are over. The proforma should record biographical, clinical and follow-up data. Follow-up will be increasingly carried out by postal questionnaire worded in a form that all patients can understand. The answers should be capable of direct entry on to a computer without any data manipulation or analysis.

The choice of a computer system assumes little computer knowledge and less enthusiasm, although this is progressively changing as consultants are appointed from a computer-literate generation. The system should be on the list approved by the Health Authority, should be able to run a 'friendly' commercial database, and should have at least 20 megabytes of hard disk storage. Computer costs are falling and will continue to fall.

Having said this, the decision about who should pay for the exercise should be clarified from the outset. Enthusiasts like Visick established follow-up systems out of their own pockets, but today most are financed by 'soft' money. As has happened in Lothian, UK, consultant commitment to audit can result in the Health Authority subsequently funding the system[6]. Few managers are likely, even in the current climate, to view this as a priority. Consultant commitment to the principle and a system bought with soft money will continue to be the most common method of starting up.

If auditing of outcome is to become widely established, however, it must have the support of the Royal Colleges. If they are to retain their role as guardians of quality control of a self-regulating profession they should ensure that only those units that practice audit are recognized as training posts. The Government, as paymaster of the National Health Service, has a vested interest in establishing formal quality control. The recommendations of the National Audit Office report *Quality of care in the NHS*[7] seem likely to be implemented.

Surgical audit is here to stay and destined to increase. The enumeration of patients seen and operations performed is a prerequisite in assessing performance of a surgical firm. Such statistics enable the rational planning of medical manpower and funds. Basic audit within a firm must be a criterion for recognition of surgical posts for training. Yet they only show one side of the coin – the quantity of workload but not the quality of care. Meaningful audit must include the assessment of outcome. This means prospective and long-term follow-up, which should be as complete as possible.

A postal questionnaire is more convenient and less time consuming for patient and surgeon and is cheaper for the National Health Service. Follow-up must also be long term. The early results of highly selective vagotomy claimed a recurrence rate of about 1 per cent after 2–3 years[8]. After 14–19 years the recurrence rate on the same patients was 30 per cent[9].

The audit of outcome therefore must be prospective, structured, long term and computer based. It is easy to establish. Its continued success requires from surgeons a commitment to the quality control of their work and from managers a modest resource allocation.

Pancreatic cysts and pseudocysts: new rules for a new game

Not many years ago the management of pancreatic pseudocysts was thought to be relatively simple, the major controversy being whether to intervene surgically immediately for external drainage or to wait until maturation for internal drainage. The issues have become more complex, and more interesting, with the development of ultrasound and computed tomographic (CT) scanning, endoscopic pancreatography and percutaneous and endoscopic sampling and drainage techniques. These technological advances have highlighted the differences between acute and chronic pseudocysts, have shown that some pseudocysts can resolve spontaneously, have helped to discriminate which are infected or likely to persist, have provided an alternative to surgical treatment in some cases, and have brought to attention that other cystic lesions of the pancreas, particularly cystic neoplasms, are more common than previously appreciated and must be recognized and treated differently from pseudocysts.

This last issue is perhaps the first to be considered. Half of the cystic neoplasms we treated during one period had been referred after another surgeon had already erroneously created a cyst–enteric anastomosis on the presumption he was draining a pseudocyst[1]. While microcystic tumours are usually benign, macrocystic tumours are probably all malignant or at least premalignant. These include cystadenocarcinomas, papillary cystic neoplasms and cystic islet cell tumours. None the less, they are usually slow growing and the majority are curable by surgical resection, large size notwithstanding. Cystic neoplasms occur more often in women, mainly of middle age. There is often a history of abdominal pain, but more and more are being found by serendipity in asymptomatic patients having ultrasound or CT scans for irrelevant reasons. These lesions are frequently large (average, 10 cm). They may be single or multilocular and can frequently be shown to be irregular or septated, or contain a solid component. The cyst wall may be calcified. The amylase content of the serum (and cyst contents) is within normal limits, in contrast to the raised levels noted in half of the sera and all of the cyst fluids of pseudocyst patients. Pancreatography characteristically shows no communication between the duct and the lumen of neoplastic cysts, whereas a communication can be demonstrated with at least two-thirds of pseudocysts. Cystic tumours, despite their probable slow progression and long natural history, should be resected in any patient fit for the operation. The diagnosis can be confirmed by cyst wall biopsy, which can be expected to show an epithelial lining. Finding this in a patient being operated on to drain a 'pseudocyst' should alter the diagnosis and the surgical strategy. Simple (non-neoplastic) cysts need no treatment, but enterogenous cysts, which occur in the head of the gland, may require resection because they can be the cause rather than the product of pancreatitis.

Pseudocysts by definition do not have an epithelial lining. They are fluid collections, usually rich in pancreatic secretions, which have escaped from a duct system disrupted by acute inflammation or obstructed by stricture or stone. The peripancreatic fluid collections commonly seen by ultrasound or CT early in acute pancreatitis are not really pseudocysts, and generally are reabsorbed without complication and without the need to be evacuated. Persistence and encapsulation occur in perhaps 5 per cent. Conversely, early pancreatic swelling (phlegmon) may develop regions of pancreatic and peripancreatic necrosis, which in turn may partially liquefy and evolve into a pseudocyst[2]. CT scanning has become invaluable for monitoring the course of these events.

Several studies have illustrated that pseudocysts occurring after acute pancreatitis behave differently from those found in chronic pancreatitis[3,4]. The former represent a complication of pancreatic necrosis, tend to occur in sicker, more unstable, patients, are more likely to become complicated by infection, haemorrhage or rupture and are less likely to have a wall thickness adequate to hold sutures for internal drainage. Paradoxically, acute pseudocysts are more likely to resolve without interventional drainage[4], but in perspective only 15 per cent of true acute pseudocysts, as distinct from acute peripancreatic fluid collections, healed spontaneously in our experience[3]. It is not known whether percutaneous catheter drainage of early acute pseudocysts will facilitate or speed healing, but the need to remove associated necrotic remains of the destructive process may ultimately determine that an operation must be performed anyway[5]. Patients who are clinically stable can be watched, but continuing signs of toxicity or suspicion of infection should mandate intervention. Percutaneous aspiration of the cyst has been proved to be accurate and safe in detecting infection when the clinical signs are equivocal[6] and catheter drainage can be used as treatment in this circumstance[7]. In general, the strategy for acute pseudocysts is to wait while the patient's condition permits and to wait no longer if he deteriorates.

Pseudocysts in chronic pancreatitis most often are found in the absence of a recent attack of acute pancreatitis. These patients are rarely acutely ill, nor do they often encounter the acute complications so much more common in acute pseudocysts. Pseudocysts of chronic pathogenesis usually have a mature capsule already present at discovery and rarely regress, perhaps never,

0007-1323/89/060533–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

if over 6 cm in diameter. Drainage is indicated in symptomatic patients and can be carried out immediately[3,4]. The natural history of small chronic pseudocysts in asymptomatic patients is not well defined, but it appears safe to observe them. Preoperative endoscopic pancreatography may have a role in the evaluation of chronic pseudocysts to ascertain associated intrapancreatic biliary stenosis as well as pancreatic duct dilation and obstruction[8]. The finding of these associated conditions may indicate the desirability of draining the bile duct and/or pancreatic duct when the pseudocyst is operated on, and indeed may bias the choice of treatment toward surgery and predicate the type of drainage procedure (i.e. resection of the pancreatic tail or cystjejunostomy plus pancreatojejunostomy, instead of cystgastrostomy).

The treatment of mature pancreatic pseudocysts can now be accomplished by various means, surgical and non-surgical. The surgeon can create an anastomosis to the stomach, duodenum, or to a Roux-en-Y loop of jejunum. The choice seems best determined by the size and location of the pseudocyst: large adherent retrogastric cysts are conveniently drained into the stomach; cysts within the duodenal sweep are often most easily drained into the duodenum; the jejunum must be brought to cysts in the pancreatic tail or those presenting inferiorly through the mesocolon, perhaps from the uncinate process. Distal pseudocysts can be resected with the pancreatic tail, and this may be preferred when the spleen is involved or there has been intracystic haemorrhage. Complication and late recurrence rates should both be low, in the order of 5 per cent or less[3,4].

However, both interventional radiologists and endoscopists have challenged the surgeon's traditional prerogative for drainage. While therapeutic needle aspiration has a high recurrence rate (about 75 per cent), prolonged percutaneous catheter drainage has had reported success rates of 70–100 per cent in small series[9,10]. Introduction of clinically important infection has been more feared than found. Occasional persistent fistulae or recurrence after percutaneous catheter drainage attest to the fact that pancreatic duct obstruction may be the underlying predisposing cause of the original 'blow-out' and of the continuing complications. I speculate that endoscopic pancreatography could be usefully predictive here: if free communication between the pseudocyst and pancreatic duct can be proved, catheter drainage may be most likely to succeed. If, on the other hand, there is a blocked pancreatic duct, it may be supposed that the pseudocyst will require a permanent alternative pathway for internal drainage.

There is a small reported experience with drainage of pseudocyst using the endoscope. It has been shown that endoscopical electrocautery can be used to cut into a pseudocyst that bulges into the gastric or duodenal lumen[11]. Stent catheters can also be placed through the wall to achieve limited internal drainage. What cannot be evaluated yet is the relative risk and efficacy of these techniques. Massive bleeding from the gut wall or a pancreatic vessel is a theoretical threat which has been realized on occasion. Non-adherence between the cyst and the adjacent gastric wall, resulting in free perforation into the peritoneal cavity, is another fearful possibility, not yet seen or perhaps just not yet reported. None the less, speaking as one who with singular lack of perspicacity once wrongly predicted that rampant disaster would result from percutaneous needle biopsy of the pancreas, I will this time take a more circumspect wait-and-see position.

The new options not only facilitate precise diagnosis but also underline its importance. The differentiation between acute and chronic pseudocysts, presence or absence of infection and necrotic debris, and associated abnormalities of pancreatic and biliary ducts all should modify the approach to treatment Even more critical, if a non-surgical treatment option is to be used, one must be certain that the lesion is a pseudocyst and not a neoplasm masquerading as one.

Leicester LE2 7LX, UK

Between 1957 and 1981, 31 716 cases of gastric cancer were registered in the West Midlands, UK. The age-standardized incidence has shown a decrease from 17·42 per 100 000 population during the first quinquennium to 15·30 per 100 000 in the last. There was an apparent increase in the proportion of proximal lesions with a decrease in the proportion of distal, antral cancers. The stage of disease at diagnosis remained constant with 79 per cent of patients having stage IV disease. Less than 1 per cent presented with stage I disease. As a result, the curative resection rate was 21 per cent. The operative mortality rates for curative partial gastrectomy and total gastrectomy were 13 and 29 per cent respectively. Surgeons undertaking more than nine total gastrectomies annually had an overall mean operative mortality rate of 22 per cent. Overall age-adjusted survival at 5 years was 5 per cent. Survival at 5 years for stage I, II and III disease was 72, 32 and 10 per cent respectively. There was a significant increase in survival time for those treated by curative resection between 1972 and 1981 compared with the previous decade. The implications for the management of gastric cancer are discussed.

Keywords: Gastric cancer, overall incidence, treatment and survival, operative mortality, resection

In 1965 a report from the Birmingham Regional Cancer Registry described the presentation, management and treatment results of patients with gastric cancer diagnosed in the West Midlands region, UK between 1950 and 1959. The overall 5-year survival rate was 4·9 per cent and this had not changed when compared with the preceding 15-year period[1]. This study was initially hospital based but became population based after 1957. Since the time of this report a number of factors have evolved which have had important implications for the treatment of gastric cancer. These include the availability of routine double contrast radiological studies and flexible fibreoptic endoscopy. In addition, improvements in anaesthetic management and in surgical techniques have been widely practised. Finally, experience from Japan has demonstrated that the adoption of recommendations[2] for careful surgical assessment and histopathological evaluation for all stages of gastric cancer can produce far better results than have been reported in the West[3].

With the background of these factors we now report the results of management of gastric cancer for the 25-year period from 1957 to 1981. During this period the Cancer Registry was wholly population based and over 95 per cent of all cases occurring in the region were registered[4]. Particular emphasis has been placed on the incidence of disease, the methods of treatment, the operative mortality for those undergoing resection and the end results of treatment.

Patients and methods

All patients registered at the Birmingham Cancer Registry with a clinical or histological diagnosis of stomach cancer between 1957 and 1981 have been reviewed Data already recorded by the Registry from patient notes include clinical features, diagnostic methods, treatment, histological findings and survival. All patients have been staged if necessary by reviewing the notes according to a clinicopathological system which takes into account histologically proven and unproven tumours (*Table 1*)[5]. In those patients not undergoing surgery, the reasons for withholding treatment have been evaluated.

Patients have been followed for a minimum of 5 years and survival has been expressed as age-adjusted survival rates This adjustment has been made in order to allow for the increasing mortality from all causes with increasing age[6]. As survival rates are particularly sensitive to the age range of the patients, and may appear unduly low when many are elderly, it is now common practice to use an age-adjusted or 'relative' survival rate, making allowance for the increase in 'natural mortality' by means of the Life Table[7] Forty patients (0·1 per cent) could not be traced to 5 years. In accordance with our usual practice these have been counted as dead at the time of the last known review. Statistical analysis was by the Student's *t* test.

Results

Incidence

During the period 1957–81, 31 716 cases of gastric cancer were registered. The population of the West Midlands has increased by 7·2 per cent during the study period[8]. However, using the 1971 population census figure of 5·11 × 10⁶ as the denominator for the whole period, this gives a crude annual incidence of 24·7 per 100 000. The incidence for each quinquennium is shown in *Table 2* The age-standardized rates clearly demonstrate a decrease in incidence following an initial rise over the first quinquennium. This rise probably reflects the improvement in data collection which occurred up to 1960. Since that time the efficiency of registration is believed to be over 95 per cent[4] The 31 716 cases included 149 cases of sarcoma, carcinoid or mixed tumours. In view of the different patterns of treatment and survival, these cases have been excluded from all subsequent analyses, leaving 31 567 for review.

The sites of disease were specified for 17 246 (54·6 per cent) cases. The remaining 14 321 (45·4 per cent) cases were either

1977–81	0·9	5·8	13·7	8·9	66·7	4·0

unspecified or involved more than one site. The percentage of cases for which the site was specified increased from 44·8 per cent in 1957–61 to 69·1 per cent in 1977–81. The specified sites have been classified as the three principal anatomical areas of the stomach: cardia, body, and pyloric antrum. Lesions have been additionally classified into other single sites. The percentage of classified cases for each site occurring during each quinquennium is shown in *Table 3*. There is an apparent increase in the proportion of proximal lesions with a corresponding decrease in the proportion of distal, antral lesions.

The distribution of stage of disease is shown in *Table 4*. There has been very little change in the incidence of stage at presentation. There is a marginal increase in the numbers of lesions amenable to palliative resection (stage IVa), with a corresponding decrease in those receiving no treatment during the later years of the study.

Treatment

The types of treatment have been classified as curative, palliative, other or none. The curative group includes all who have had a resection with intent to cure and by definition had stage I–III disease. The palliative resection group were stage IVa and, again by definition, the remaining patients were stage IVb (*Table 5*). The laparotomy rate for the whole group was 55·6 per cent, with curative resection being undertaken in 6588 or 20·8 per cent of all patients. However, no treatment was carried out in 13 409 or 42·5 per cent of the whole group.

Operative mortality

Resection was undertaken in 9247 (29·3 per cent) patients; for cure in 6588 (20·8 per cent) and for palliation in 2659 (8·4 per cent). In the curative group, total gastrectomy was done in 1330 (20·2 per cent) and partial gastrectomy, including proximal and distal procedures, in 5258 (79·8 per cent). The operative mortality, defined as death within 30 days of operation, for these patients is shown in *Table 6*. For total gastrectomy the overall operative mortality was 28·8 per cent and for partial gastrectomy it was 13·0 per cent. For comparison, the operative mortality rates for palliative resections were 36·6 per cent for total gastrectomy and 23·0 per cent for partial gastrectomy. Furthermore, the 30-day mortality rate for those undergoing laparotomy alone was 35·8 per cent, contrasting with a rate of 49·0 per cent for those receiving no treatment.

These rates have been calculated for the whole study period. Analysis of the rates by quinquennium has demonstrated that there is no obvious improvement or deterioration in recent years.

In an attempt to determine factors influencing the outcome of surgery, the experience of surgeons has been evaluated. Experience has been evaluated for all gastrectomies, curative or palliative and total or partial. The number of curative gastrectomies performed annually by each surgeon has been calculated (*Table 7*). The median number of resections was 4·6 per year; thus 50 per cent of all resections were done by surgeons doing less than five procedures per year. For partial gastrectomy

Table 5 *Distribution by type of treatment*

Treatment	No. of cases	Distribution (%)
Curative resection		
Total gastrectomy	1330	4·2
Partial gastrectomy	5258	16·6

the operative mortality rates were not influenced by the number of procedures performed, and approximated to the overall figure of 13 per cent (*Figure 1*). For total gastrectomy, however, the operative mortality declined with the increasing frequency of operation. Thus for those surgeons performing an average of more than nine resections per year the operative mortality rate was 21·6 per cent (134 resections) compared with 30·8 per cent (795 resections) for those performing six or less ($t=2{\cdot}16$ $P=0{\cdot}05$; *Figuere 1*).

Reasons for treatment

Factors influencing the selection of treatment are difficult to determine from a retrospective study such as this. However, data are recorded which demonstrate why curative treatment was not undertaken (*Table 8*). All patients included in this category had stage IV disease by definition of the clinicopathological staging system used in this study[5] as they had gross residual disease. To a certain extent, staging of these patients has been more dependent on clinical parameters alone as less than half had a laparotomy (*Table 5*).

The commonest contraindication to curative treatment was the extent of disease ($n = 19\,728$, 79·0 per cent) which included both locally advanced lesions and distant metastatic disease. Poor general condition, treatment refusal and diagnosis at autopsy accounted for most of the remainder ($n = 4815$, 19·3 per cent)

The effect of age has also been assessed for its part in treatment selection. As age increased the proportion of patients not undergoing curative treatment also increased (*Figure 2*). Although a decrease in the extent of disease and an increase in those in poor health appear to account for the effect of age on treatment (*Figure 3*), a direct relationship should not be inferred. In the analysis of the Registry records only one of the principal contraindications to curative treatment has been documented. Thus it is likely that many in poor health would also have had advanced disease, and the decrease in the extent of disease could be an apparent rather than true phenomenon.

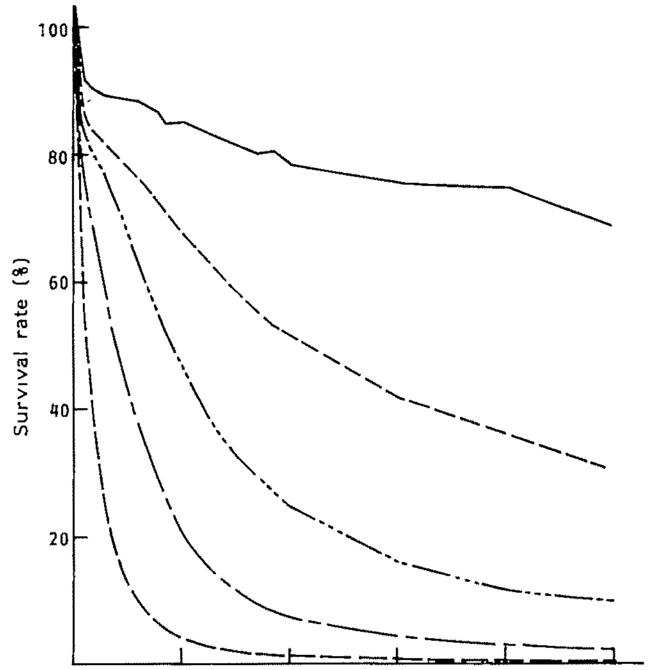

Figure 4 *Overall 5-year survival by stage of disease*. ——, *Stage I*, ---, *stage II*,-----, *stage III*, ---, *stage IVa*; ---, *stage IVb*

Survival

The overall 5-year survival was 4·5 per cent. Analysis of survival by quinquennium has shown an increasing trend from 3·8 per cent in 1957–61 to 5·2 per cent for 1977–81. Survival by stage is shown in *Figure 4*. Patients with lesions amenable to curative resection have 5-year survival rates of 72, 32 and 10 per cent for stages I, II and III respectively More distally situated lesions were associated with a better survival than were proximal tumours for antral lesions the survival rates were 75·8 per cent for stage I, 35·5 per cent for stage II and 11·8 per cent for stage III; for cardia survival rates were 23 3 per cent for stage II and 4·9 per cent for stage III. (The number of stage I tumours of the cardia ($n = 7$) was too few for assessment.)

Survival by treatment demonstrated an overall rate of 9·5 per cent for curative total gastrectomy and 22·7 per cent for curative partial gastrectomy. During the study period survival tended to improve for both procedures (*Table 9*). Although the differences in overall survival for both procedures did not reach statistical significance, this trend became significant for partial gastrectomy after exclusion of the operative deaths. Furthermore, when cases are stratified by stage, the results of curative resection (i e. combining both partial and total gastrectomy) show an improving survival trend. Again after exclusion of the operative deaths, both differences reach statistical significance at the 5 per cent level and if all curative resections are considered together, including those in which the stage is not known, the improvement in survival reaches significance at the 1 per cent level.

Analysis of survival by age for each of the stages demonstrates consistent rates for all ages (*Figure 5*), suggesting that the survival effect of age *per se* is minimal.

Since the majority of patients had advanced disease, the results of palliative treatment are of interest. For patients undergoing palliative resection, survival to 12 months was 21 per cent, falling to 7·4 per cent at 2 years. Overall, those with unresectable lesions had a 6 per cent chance of surviving 12 months, with those undergoing intubation faring worse than those having a laparotomy only. This probably reflects a higher proportion of proximal lesions in the intubation group, which, as has been shown, had a worse prognosis.

Discussion

The findings in this large series reflect the pattern of presentation and management of gastric cancer in one region in the UK. As with the previous report from this region[1], there is little in the literature to suggest that the overall approach to gastric cancer in the West Midlands differs from the rest of the UK. While it is fully recognized that this is a retrospective analysis and that important contributing factors to the full picture may be unavailable, its strength lies in the large numbers, the quality of the data and its population basis, all of which obviate the

possible bias present in even the largest hospital series. Hence a number of conclusions can be made that, in the context of the current trend towards the adoption of the Japanese approach to gastric cancer[3,9], are worthy of general discussion.

In both western Europe and the USA the incidence of gastric cancer has been decreasing[10]. In this study, despite the increasing age of the population during the period under review, the age-standardized incidence has shown a similar decrease. Analysis of the data also suggests an increase in the proportion of proximal lesions with a corresponding decrease in distal, antral tumours. These differences are currently being further evaluated. In series from the USA, a far greater increase in the proportion of proximal lesions has been reported[11]. This has been concurrent with an increase in the incidence of diffuse-type tumours. It may be that dietary changes with a reduction in stored and preserved foods have reduced the intake of harmful nitrates and hence the exposure of the distal stomach to carcinogens. As a result, the proportion of proximal lesions has increased relatively.

The most striking feature of this series is the constancy of the stage of disease at presentation. Throughout the study period, 80 per cent of patients have had disease considered to be too extensive for radical surgery. Similarly, the proportion of patients with stage I disease has remained constant at 0·7 per cent. Other reports have demonstrated a recent increase in the incidence of early lesions describing rates of 10–12 per cent[12,13]. Such increases have been attributed to the widespread use of upper gastrointestinal endoscopy. This has been similarly widely available in the West Midlands during the latter half of the study, yet without a corresponding increase in incidence Those studies reporting greater incidence originate from single centres and do not reflect the overall pattern of practice in a defined population.

Referral patterns should therefore change. Early endoscopic assessment should be encouraged, such that patients with any symptoms referable to the upper gastrointestinal tract are investigated, as opposed to only those with the established symptoms of gastric cancer who commonly have advanced disease and currently comprise the group referred for endoscopy. It is not possible, however, to be more specific about the important symptoms, as studies from our programme for the early detection of disease[14] have failed to correlate any symptom with the extent of disease[15].

The high proportion of patients with advanced disease is reflected in the poor overall survival, which differs little from the previous report from this registry[1]. However, the improvement in survival for curative resection does offer some encouragement. As the operative mortality has shown little change throughout the study period, the explanation for this improving trend is conjectural. Preoperative assessment and postoperative support may be important, although these would be expected to influence operative mortality. It is possible that anaesthetic advances have allowed more radical procedures to be undertaken and thus, for those surviving the operation, greater tumour clearance has increased the chances of disease-free survival.

The numbers of patients dying in the postoperative period is of particular concern, especially in the context of the current Medical Research Council trial of extended gastrectomy and lymphadenectomy[9]. The results of the analysis of the frequency of gastric resection by individual surgeons highlight the importance of experience, particularly in total gastrectomy. Whether this is a reflection of technical expertise, better patient selection or improved pre- and postoperative management is difficult to determine from a retrospective study such as this Nevertheless, the operative mortality rates achieved by those surgeons in the West Midlands most frequently performing total gastrectomy compares poorly with that reported by specialist centres in Europe and Japan. Pichlmayr and Meyer[16] in the FRG report an operative mortality rate for total gastrectomy of 8 per cent and the overall Japanese figure is 3 per cent[17]. Furthermore, recent series from individual surgeons with an interest in gastric surgery clearly demonstrate acceptably low operative mortality rates following radical resection. In personal series of radical resections from UK surgeons, operative mortality rates of 5 per cent[18] and zero[19] have been reported. In addition, a 30-year study from one institution in the USA describes an operative mortality rate of 11 per cent for curative gastrectomy associated with a curative resection rate of 1·6 procedures per year[20]. Thus, although operator frequency may in part improve operative mortality rates, a strong case can be made for the development of specialist referral centres in which interested, experienced surgeons with appropriate supporting staff are regularly undertaking radical resections. This would enable standardization of management, surgical procedure and pathological documentation not only to produce the optimal outcome for our patients but also to improve understanding of the natural history of gastric cancer

Gastric cancer remains a major management problem. This study has described treatment and results which are probably typical for the whole country. Improvements are only likely with earlier detection and, with the current incidence of disease, this can only be applied to symptomatic patients. Nevertheless, early assessment of any upper gastrointestinal symptom needs to be emphasized to all involved in the management of such patients. In addition, for such an approach to succeed the early results of curative surgery need to be free from major morbidity and mortality and should only be performed in specialized centres.

Acknowledgements

Technique for abdominal radical total gastrectomy

J. F. Chester and J.-C. Gazet

St. George's Hospital, Blackshaw Road, London SW17 0QT, UK

Correspondence to: Mr J.-C. Gazet

Abdominal radical total gastrectomy for cancer involves mobilization of the stomach, spleen, greater omentum and contiguous lymph-drainage areas. Conventional dissection commences lateral to the spleen, which is mobilized medially, with subsequent stripping of peritoneum over the pancreas, and identification of the coeliac trunk and left gastric artery. The dissection proceeds along the greater and lesser curves of the stomach after division of the omental attachments to the colon, and the duodenum is divided distal to the pylorus. Division of the oesophagus is usually undertaken immediately before delivery of the specimen.

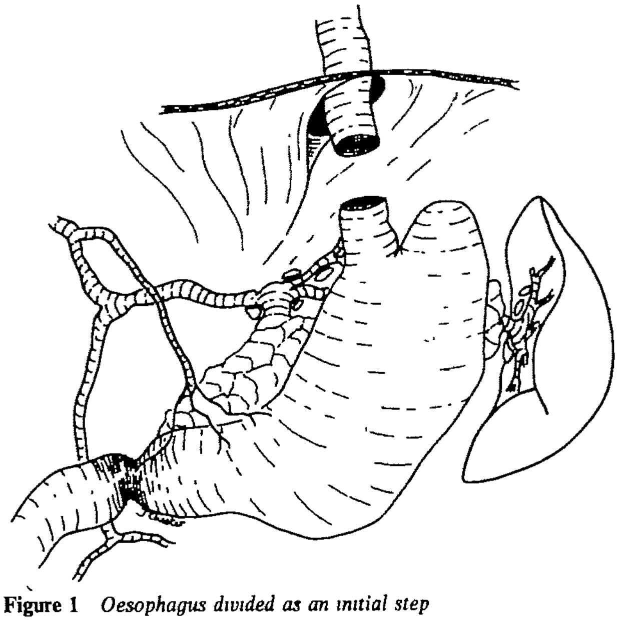

Figure 1 *Oesophagus divided as an initial step*

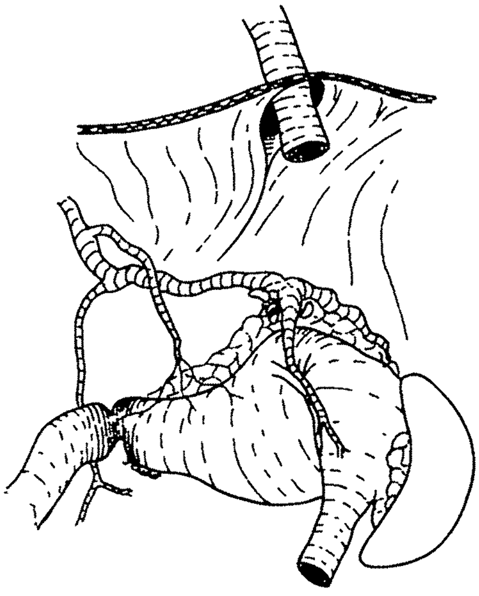

Figure 2 *Specimen displaced to display coeliac trunk and left gastric artery*

Technique

Our modification of abdominal radical total gastrectomy, which has now been used in over 100 patients, involves an initial assessment and confirmation of operability, with subsequent immediate mobilization and division of the oesophagus at the diaphragmatic hiatus (*Figure 1*). Inferomedial displacement of the specimen after division of the lienorenal ligament and mobilization of the spleen is then undertaken Using this technique, the left gastric artery and coeliac trunk are easily identified (*Figure 2*), and delivery of the stomach and surrounding lymphatic drainage areas is safer, quicker and easier.

Controlled trial of heater probe treatment in bleeding peptic ulcers

A prospective randomized controlled trial of endoscopic heater probe therapy in bleeding peptic ulcers was performed to determine whether probe therapy can reduce rebleeding rates. Of 630 patients endoscoped for suspected upper gastrointestinal haemorrhage over a 16-month period, 166 (26 per cent) were found to have a peptic ulcer. Either minor or no stigmata of recent haemorrhage were found in 115 patients at the time of endoscopy. A single peptic ulcer with either active haemorrhage or a visible vessel was found in 51 patients, 43 of whom were entered into the trial. There were eight exclusions: four were inaccessible, one was a torrential haemorrhage and three were excluded for non-technical reasons. Patients were randomized to receive either heater probe ($n = 20$) *or sham* ($n = 23$) *therapy. In actively bleeding ulcers, immediate haemostasis was achieved following probe therapy in 14 of 18 patients (78 per cent) compared with none of 21 having sham treatment* ($P < 0{\cdot}002$). *No rebleeding occurred in the probe therapy group* ($n = 20$) *compared with rebleeding in five of 23 sham treated patients* ($P = 0{\cdot}05$). *Urgent surgery for haemostasis was required in three of the five sham treated patients who rebled. It is concluded that heater probe therapy may be effective in reducing rebleeding rates in peptic ulcers accessible to the endoscope.*

Keywords: Peptic ulcer haemorrhage, endoscopic therapy, heater probe

The mortality rate of upper gastrointestinal haemorrhage remains around 10 per cent despite advances in diagnostic and resuscitation techniques[1,2]. Much of this mortality relates to rebleeding in an increasingly elderly population[2]. If advances are to be made in the treatment of these high-risk patients, satisfactory non-operative methods of preventing rebleeding must be developed. Of the currently available endoscopic thermal methods only the laser has shown clear benefit[3–6]. Lasers, however, are expensive, non-portable and are unlikely to be widely available. The heater probe is a transendoscopic thermal device which is relatively inexpensive, portable and, in experimental tests, produces vessel coagulation with less tissue erosion than seen with other currently available thermal devices[7–9].

A prospective, randomized controlled study assessing the efficacy of the heater probe in the management of patients with bleeding peptic ulcers is reported.

Patients and methods

All patients admitted to the Western Infirmary, Glasgow with acute upper gastrointestinal haemorrhage over the 16-month period of the trial (from August 1986 to November 1987) were considered for inclusion. Patients presenting with haematemesis and/or melaena routinely had endoscopy within 24 h of admission by an experienced member of the Haematemesis Management Team. Potentially eligible patients were diagnosed endoscopically to have a single peptic ulcer in the stomach, pyloric canal or duodenal cap, and no other significant upper gastrointestinal source of blood loss such as oesophageal varices, carcinoma or multiple bleeding erosions. When a patient was recognized to be potentially eligible for study entry, the ulcer was assessed by the heater probe endoscopist (G.M.F.). The patient was only deemed eligible for entry into the study if the following criteria were also met: (1) actively bleeding sites on the ulcer before or after washing, and/or (2) a visible vessel in the ulcer base before or after washing, and (3) confirmed accessibility of the heater probe to the source of blood loss. Active bleeding was defined as a continuous flow of blood from the ulcer base continuing for the duration of the endoscopy. A visible vessel was defined as an elevated red or blue spot, a pulsatile pseudoaneurysm or active arterial spurting. These endoscopic criteria are known to be associated with the highest risk of rebleeding[10–13].

Patients who fulfilled these criteria were then stratified for age (<60 and ⩾60 years), shock (systolic blood pressure <100 mmHg, pulse >100/min: present/absent on admission) and ulcer site (gastric/duodenal). Randomization was carried out within each group, a sealed envelope being opened to indicate either heater probe or sham therapy.

Heater probe therapy was performed by a single operator (G.M.F.) using an Olympus GIT-IT10® (Olympus Corporation, Tokyo, Japan) endoscope and Olympus Heatprobe Unit with CD 10Z heater probe (3·2 mm outer tip diameter; *Figure 1*). The heater probe is an endoscopic contact thermal device which has an internal silicon chip controlled heating element linked to a computerized power source. Thermal energy is transferred by conduction through the probe tip at variable energy settings (5–30 J) each delivered as a 7-s pulse. The probe tip is Teflon® (E. I. du Pont de Nemours and Company, UK) coated which reduces tissue adherence.

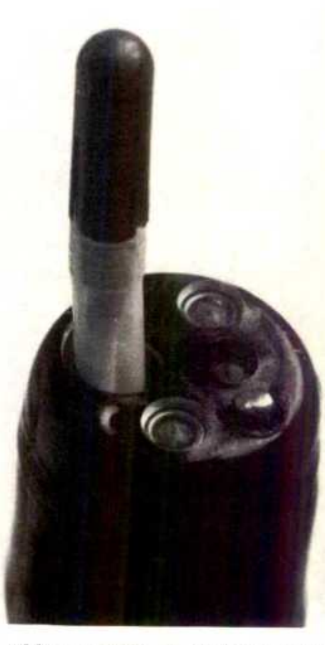

Figure 1 *View of heater probe tip (3·2 mm outer diameter) with an Olympus GIF-IT10 endoscope*

Duodenal ulcer
Visible vessel
Coagulated tissue 'foot print' from single heater probe application

Figure 2 *Endoscopic appearance of a visible vessel in a duodenal ulcer base after a single heater probe application*

The heater probe technique used was that recommended by Johnston *et al.*[14]. With active haemorrhage, the probe was used to tamponade the bleeding point until haemostasis was achieved. The probe, through its proximal water ports, allowed continuous washing during tamponade which helped to indicate when haemostasis had been successful. The heater probe was then activated at the 25 J setting and further therapy applied until complete haemostasis was secured. In the absence of active bleeding, a clot overlying an ulcer was washed until the underlying bleeding point or visible vessel was seen. After this, cautery was applied as described above (*Figure 2*). On average seven applications per patient, delivered at a 25–30 J setting, were required to achieve complete haemostasis. The maximum number of applications in any patient was ten at the 25 J setting. Sham therapy consisted of the heater probe being held inactivated in the gut lumen. Only the endoscopist was aware of which treatment each patient had received and he took no further part in their management.

Following endoscopy, patients were managed by members of the team unaware of the initial randomization, and their progress was documented until discharge or death. All patients received H_2-receptor antagonist therapy (ranitidine 50 mg IV 6-hourly) and blood transfusion where deemed appropriate by the attending clinician. Rebleeding was diagnosed by team members if one of the following features was present:

1. Fresh blood in the upper gastrointestinal tract at re-endoscopy or surgery
2. Vomiting fresh blood at any time other than immediately after endoscopy where fresh blood had been noted
3. Fresh melaena plus one of the following:
   (a) Haemodynamic and clinical evidence of hypovolaemic shock (systolic blood pressure < 100 mmHg, pulse rate > 100/min)
   (b) A falling haemoglobin despite blood transfusion (failure to raise haemoglobin by more than 0·5 g/dl per unit of blood transfused).

Surgical intervention for haemostasis was undertaken when deemed appropriate by the attending surgeon.

Quantitative data (expressed as mean ± s.e.m.) were analysed by the unpaired, two-sided Wilcoxon rank sum test. Integral data were compared by the Fisher's exact test. Significance was taken at the 5 per cent level ($P \leqslant 0{\cdot}05$).

All patients gave written, informed consent and the study was approved by the local hospital ethical committee.

Results

During the 16-month trial period (from August 1986 to November 1987), 630 patients presenting with suspected acute upper gastrointestinal haemorrhage had endoscopy within 24 h of presentation to the Western Infirmary, Glasgow. One hundred and sixty-six (26 per cent) were found to have a peptic ulcer. Of these, 115 (69 per cent) had either no stigmata of recent haemorrhage or minor stigmata (flat black/red spots) at the time of endoscopy. This group was deemed a low-risk group in terms of rebleeding but their progress was also documented until discharge. None of these patients rebled. A single peptic ulcer with either active haemorrhage or a visible vessel was found in 51 patients, 43 of whom were entered into the trial. There were eight exclusions: four high, lesser curve gastric ulcers were inaccessible to endoscopic treatment and were therefore not randomized; the endoscopist was not available for two patients; in one patient there was torrential arterial haemorrhage from a posterior wall duodenal ulcer necessitating immediate surgery; and in one patient the attending surgeon had decided on immediate surgery after endoscopy and therefore this patient was not randomized. Of the four patients excluded because of inaccessibility, four rebled, three required emergency surgery for haemostasis and two died.

Of the 43 patients entered into the trial 20 were randomized to receive heater probe therapy and 23 sham therapy. Both groups were well matched with regard to clinical and endoscopic criteria known to influence prognosis (*Table 1*). Nine patients in the heater probe group and nine patients in the sham group had serious coincidental disease.

In patients actively bleeding at the time of endoscopy, immediate haemostasis was achieved in 14 of 18 heater probe patients compared with none of 21 patients having sham treatment ($P < 0{\cdot}002$). The post-treatment blood transfusion requirements (units packed cells) were 1·7 ± 0·4 (mean ± s.e.m.) in the probe group and 2·8 ± 0·6 in the sham group. Mean non-operative hospital stay (mean ± s.e.m.) was 4·1 ± 0·2 days in the probe group and 4·4 ± 0·4 days in the sham group. No rebleeding occurred in the probe treated group ($n = 20$) while five of the 23 sham treated patients rebled ($P = 0{\cdot}05$). Surgery for haemostasis was required in three of these five sham treated patients who rebled. No patient died.

When endoscopic characteristics were assessed, none of the seven ulcers with visible vessels rebled in the heater probe group while three of four rebled in the sham treated group. Considering all untreated ulcers with a visible vessel in the study, seven of eight (88 per cent) rebled, compared with none of the seven having probe therapy ($P < 0{\cdot}04$). In ulcers with active oozing, none of the 13 in the probe group rebled while two of 19 rebled in the sham group.

One perforation occurred 3 h after heater probe treatment in a 76-year-old man who had an actively bleeding anterior wall duodenal ulcer. He had prolonged endoscopy and had a total probe application of 250 J. At laparotomy, a clean acute anterior duodenal perforation was noted with no macroscopic evidence of thermal-induced perforation. A truncal vagotomy and pyloroplasty were performed and he made an uncomplicated recovery.

Discussion

This study has demonstrated that heater probe therapy reduces rebleeding rates in patients presenting with acute upper gastrointestinal haemorrhage from peptic ulcers with endoscopic criteria suggesting a high risk of rebleeding.

As the population presenting with acute upper gastrointestinal haemorrhage ages, there is a need for a simple, inexpensive and effective endoscopic therapy for peptic ulcer haemorrhage. Endoscopic injection therapy with adrenaline and polidocanol[15] or adrenaline alone[16] has recently been used to treat peptic ulcer haemorrhage and has shown convincing benefit in producing immediate haemostasis and reducing the requirement for emergency surgery. Further controlled studies assessing these treatment regimes are required to confirm these findings. The heater probe is small, portable and relatively inexpensive (6200 pounds sterling). In addition, it has specific technical advantages over other currently available endoscopic thermal devices. Firstly, it has a powerful washing facility which, by improving visibility, allows accurate targeted therapy, directly on to the bleeding site. Secondly, the heater probe produces coagulation by combining heat and pressure simultaneously (coaptive coagulation) resulting in more effective haemostasis with less tissue erosion[9]. This compares favourably with laser photocoagulation which requires tissue heating alone to induce vessel shrinkage (zonal heating)[9]. Thirdly, the probe, unlike other thermal devices, can be applied and activated tangentially, allowing better access to difficult ulcers. Disadvantages encountered with the heater probe are few, although with any device requiring physical pressure to produce vessel tamponade there is always the risk, albeit small, of visceral perforation. Several experimental studies have confirmed the heater probe to be the safest and most effective thermal device currently available[7–9]. In our study the maximum energy application to any patient was 250 J (10 × 25 J), although increased energy loads have been reported in the treatment of peptic ulcer bleeding without complications[14,17].

The results of our study differ from a preliminary report by Matthewson and his colleagues where a laser, but not a heater probe, showed a benefit over controls[18]. The studies are not entirely comparable in that their randomization was biased towards probe therapy and, in addition, data from previous laser work were recruited to improve the significance of laser over probe treatment. A previous uncontrolled study by Johnston *et al.* showed the probe to be more effective than the Nd-YAG laser in producing haemostasis[14].

In evaluating new endoscopic therapeutic methods in upper gastrointestinal haemorrhage it is important to identify and study only patients at high risk of rebleeding, where benefit from an interventional treatment regime may be seen early. Our study evaluated only patients who were either actively bleeding or who had visible vessels, both high-risk factors in predicting rebleeding[11–13]. In our study the rebleeding rate of untreated visible vessels was 88 per cent, confirming the significance of this endoscopic feature. In contrast, no rebleeding was noted in the seven visible vessels treated with the heater probe, emphasizing the efficacy of the probe in treating these lesions.

The single operator aspect of our study is another feature which deserves emphasis, particularly in discussing the assessment of new endoscopic techniques. A single operator study will contain less 'learning period' bias than an equivalent multioperator trial and should therefore provide a more accurate evaluation of the technique. This view is supported by previous single operator studies[5,19] where the overall results using identical equipment tend to be better than in similarly designed multioperator trials[20–22]. Any new endoscopic thermal device should be sufficiently simple and effective to be used in the clinical situation by several operators. The heater probe fulfils these criteria and, since the end of the current study, has been used effectively by other endoscopists.

Although our study showed a reduction in rebleeding rates following heater probe therapy, we also noted a small group of patients with endoscopically inaccessible ulcers who fared particularly badly, with a high rebleeding and operation rate. Ulcer inaccessibility has also been a consistent problem in other studies assessing varying endoscopic methods[3,5,19–21] and is clearly the limiting factor with most of the currently available endoscopic techniques. Accessibility may be improved by developments in therapeutic endoscopes or modifications of the thermal devices themselves.

We feel that heater probe therapy is of significant benefit in the treatment of patients with major peptic ulcer haemorrhage, although this will require confirmation in further controlled trials. The heater probe size and cost make this device a practical proposition for all units involved in the management of peptic ulcer related upper gastrointestinal haemorrhage.

Acknowledgements

We wish to thank the Haematemesis Management Team members (Mr F. Kennedy, Mr C. MacKay, Dr K. E. L. McColl and Dr J G. Allan) for their co-operation in this study. Our thanks also to KeyMed Ltd., Southend-on-Sea, UK, for lending the heater probe equipment, and to Mrs D. Park for typing the manuscript.

Vascularization of small liver metastases

The portal vein contributes little to the blood supply of established liver metastases in the presence of a patent hepatic artery. However, its role in the perfusion of early metastatic liver disease remains controversial. We have quantified the relative contribution of the portal vein and hepatic artery to the internal circulation of small liver tumours. These studies were conducted in a new rat model of liver metastases generated by the intraportal injection of cultured tumour spheroids. A total of 633 lesions were studied in 18 animals using radioisotope tracer microspheres. Nodules ranged from 0·5 to 6·0 mm in diameter, 92 per cent being 3·0 mm or less. The ratio of radioactivity in tumour compared with normal tissue (T:N ratio) was determined after simultaneously injecting microspheres into the portal and arterial circulation of each animal. The mean hepatic artery T:N ratio was significantly greater than that of the portal vein for all tumour sizes studied (P < *0·01). Nodules 0·5 mm in diameter had a mean (s.e.m.) hepatic artery T:N ratio of 1·50 (0·12) in comparison with a mean portal vein ratio of 0·13 (0·04). Tumour nodules 2·0 mm in diameter had a mean (s.e.m.) hepatic artery T:N ratio of 1·26 (0·11) in comparison with a mean portal vein ratio of 0·06 (0·01). The overall T:N ratio for both routes decreased with increasing tumour size. These results indicate that hepatic tumours as small as 0·5 mm already have an established internal vasculature perfused predominantly by the hepatic artery. In contrast, the portal vein contributes insignificantly to the internal perfusion of these lesions. These results have significant implications for adjuvant locoregional therapy in gastrointestinal cancer.*

The role of the portal vein in the perfusion of liver metastases is controversial. It has been shown both experimentally and clinically that it has little function in the nutrition of large tumours in the presence of a patent hepatic artery[1–3]. In contrast, the contribution of the portal venous circulation to the nutrition of early metastatic liver disease is poorly understood. Whilst there is agreement that it nourishes micrometastases by diffusion, the evidence for direct portal vascularization of small clinically undetectable liver metastases is conflicting[4–9]. This must be quantified in order to understand the full potential of adjuvant therapy in gastrointestinal cancer.

The study of blood flow in small liver metastases in patients is not possible with the limited resolution of present imaging techniques. Accordingly, clinical data relate to relatively large lesions, in which the hepatic artery has been shown to be the major blood supply[4]. Metastatic liver disease has been studied in patients at post-mortem examination, but these results may not reflect perfusion under physiological conditions. Nevertheless, injection studies in cadaver specimens demonstrate a mixed circulation in metastases less than 1·0 cm in size in which the arterial component predominates[5,6].

Perfusion of small liver tumours has been assessed in a number of experimental animal models. Tumours generated in rats by direct intrahepatic implantation have been shown to derive part of their blood supply from portally filled vessels either within or encircling the lesion[7,8]. Hepatic arterial ingrowth is well established by the time these lesions reach 2·0 mm in diameter[7,8]. Similarly, chemically-induced primary hepatocellular carcinomas in rats seem to derive nutritive flow from the portal vein up to a size of 2·0 mm[9].

Although the above studies suggest at least some portal vein perfusion of liver metastases up to a few millimetres in size, they do not quantify this in relation to the hepatic artery. As the perfusion characteristics of tumours can vary widely, a large number of lesions of comparable size need to be assessed. We have achieved these aims in a rat model of liver metastases generated by the intraportal injection of cultured tumour spheroids.

Materials and methods

Animals

Inbred male Wistar WAG rats weighing between 250 and 280 g were obtained from the Animal Resources Centre at Murdoch University, Western Australia. The animals were fed standard rat pellets and water *ab libitum* and allowed a period of 7 days acclimatization. All experiments on animals were conducted in accordance with the guide-lines of the National Health and Medical Research Council of Australia.

Cell culture on microspheres

The cell line 192 NRc was derived from a 1,2-dimethylhydrazine (DMH)-induced colonic carcinoma in Wistar WAG rats. The supply of tumour for culture was established by intramuscular hindlimb implantation and freezing down a large quantity of solid material at −70°C from the second passage generation.

Microspheres used for culture were positively charged polystyrene ion exchange resins (Dowex 2, The Dow Chemical Company, USA), sized to 45–75 μm in diameter Equal aliquots of microspheres were washed in Hank's solution (without Ca^{2+}, Mg^{2+}) and then autoclaved When cultured with RPMI 1640 media (Flow Laboratories, North Ryde, New South Wales, Australia), penicillin 100 units/ml, streptomycin 100 μg/ml and 5 per cent fetal bovine serum, the cells covered each microsphere in a firmly attached monolayer. The tumour spheroids were washed in RPMI 1640 to remove free cells from suspension and diluted to an appropriate concentration for injection.

Induction of liver metastases

The detailed description of this model has been previously reported[10]. The portal vein of 18 rats was injected with either 5×10^4 or 1×10^5

tumour spheroids to produce discrete hepatic tumours in varying numbers. Perfusion of tumour nodules was assessed over a time period ranging from 11 to 19 days after inoculation of the cancer spheroids. The growth characteristics of this model indicate that lesions sampled during this time interval would range from 0·5 to 7·0 mm in diameter[10].

Blood flow measurements

A standard tracer microsphere technique was used to quantify the perfusion of individual tumours. The carotid artery and portal vein of each animal was cannulated with a polyethylene catheter (SP8, Dural Plastics and Engineering, Auburn, Australia). A homogeneous suspension of radioisotope-labelled microspheres was obtained by mixing between two syringes through a three way tap. Simultaneous injections over 30 s of 2×10^6 ^{57}Co and 6×10^5 ^{113}Sn or ^{125}I microspheres were administered into the left ventricle and portal vein respectively.

Preliminary experiments in normal animals confirmed that there was maximal trapping of tracer microspheres in tissue. After left ventricular injection of microspheres, 0·2 per cent of the total counts in the gastrointestinal tract were detected in portal blood. Similarly, only 0·01 per cent of the total liver counts were detected in systemic arterial blood after portal vein administration.

Tracer sphere injections into the portal venous and hepatic arterial circulation of tumour-bearing animals were carried out as described above. Five minutes later, 1·0 ml 50 per cent Indian ink (Reeves Educational Colours, Pty Ltd., Victoria, Australia) was infused into the inferior vena cava to demarcate hepatic tumour nodules. The carbon particles in the ink are phagocytosed by the Kupffer cells of the reticuloendothelial system of normal liver parenchyma. The livers were removed and fixed in Fekete's solution (formalin, acetic acid and ethyl alcohol). Individual lobes were separated and sectioned at 1·0-mm intervals, tumour appearing as discrete white nodules against a dark parenchymal background.

Nodules were dissected out under magnification, care being taken to remove all adherent liver tissue. The maximum diameter of each tumour was recorded to the nearest 0·5 mm and its mass determined to within ±0·05 mg (Sartorius balance, Sartorius-Instruments Ltd., UK). The activity for each isotope was measured in a three channel γ counter (Packard Instrument International S.A., Zurich, Switzerland). Individual tumour nodules and the normal liver tissue from each lobe were counted separately.

Relative perfusion of tumour nodules was expressed as the ratio of the weight specific counts for the lesion and the normal liver tissue from the lobe of origin (T.N ratio).

Statistics

The statistical significance of observed differences between the portal vein and hepatic artery T.N ratios were analysed using a two-tailed Wilcoxon signed rank test.

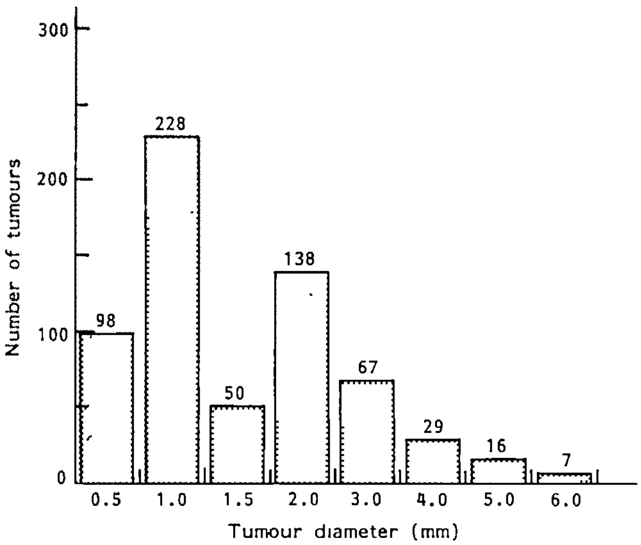

Figure 1 *Frequency distribution of 633 liver tumours examined in 18 rats according to tumour size*

Results

Tumour growth

All animals injected with tumour spheroids developed multiple hepatic nodules. The total number of liver tumours in each of the 18 animals studied varied from a minimum of four to a maximum of 120 (*Table 1*). Rats killed at 12 days from inoculation had a mean (s.e.m.) tumour diameter of 1·33 mm (0·04). Nodules studied at 19 days had a mean diameter of 4·1 mm (0·37). Relative perfusion was assessed in a total of 633 tumours ranging from 0·5 to 6·0 mm in diameter. Their distribution according to diameter is illustrated in the frequency histogram in *Figure 1*. Of the tumours, 92 per cent were 3·0 mm or less in diameter.

Blood flow studies

Injections of tracer microspheres via either vascular route resulted in excess of 10^4 spheres per gram of normal liver tissue. *Table 1* lists the mean hepatic artery and portal vein T·N ratios for each animal. The mean T·N ratios following portal vein administration were all $\leqslant 0·27$. In contrast, the mean hepatic

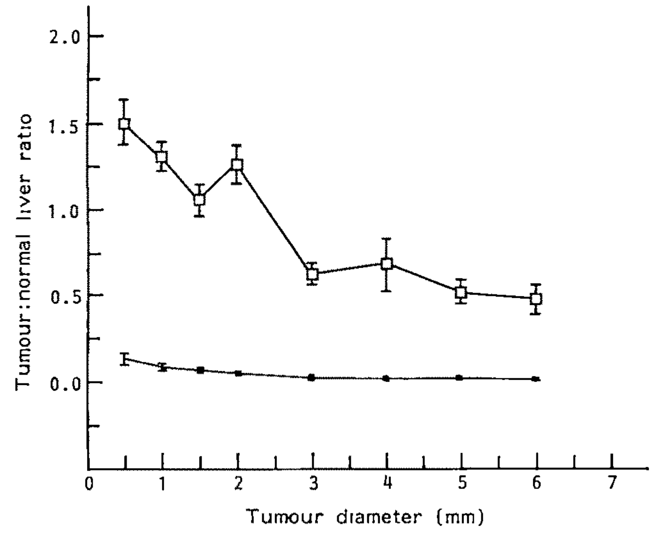

Figure 2 *Tumour normal liver ratios after injection of radioactive tracer microspheres into the arterial (□) and portal venous (—) circulation of each animal; each point is the mean and standard error of all tumours studied at that diameter*

artery T·N ratio was significantly greater than that for the portal vein in all animals, the lowest mean value being 0 6 (rat 14).

The relationship between perfusion and tumour size is illustrated in *Figure 2* where the data for all animals have been combined. There is about a 20-fold difference between the mean portal and hepatic T·N ratios at all tumour diameters ($P < 0{\cdot}01$). These results indicate that small 'secondary' liver tumours were not significantly vascularized by the portal vein. In contrast, the smallest lesions studied (0·5 mm) had an established internal circulation perfused predominantly by the hepatic artery (mean T:N ratio of 1·50). As diameter increased, overall tumour vascularity diminished. Nodules greater than 2 0 mm in diameter were hypovascular in comparison to the normal liver parenchyma. There was no histological evidence of tumour necrosis in the larger tumours.

Discussion

A study of the perfusion of small experimental liver metastases has been carried out in Wistar WAG rats. Multiple discrete liver tumours were produced in these animals by the injection of tumour spheroids into the portal vein. Spheroids were obtained by the culture of a DMH-induced colonic carcinoma cell line on to the surface of polystyrene microspheres. Using a standard radioisotopic microsphere technique, we have been able to quantify the relative perfusion of 633 tumour nodules ranging from 0·5 to 6·0 mm in diameter.

The most important finding has been that there was negligible trapping of microspheres in small liver tumours following portal vein injection (mean T.N ratios $\leqslant 0{\cdot}13$). In contrast, the smallest lesions studied (0·5 mm) had already developed a rich internal circulation perfused almost exclusively by the hepatic artery (mean T:N ratio 1·50).

Other experimental studies investigating the role of the portal vein in the perfusion of small liver tumours differ in their findings. Conway *et al.* demonstrated diffusion of portal nutrients into chemically-induced hepatocellular carcinomas up to 2·0 mm in diameter in rats using optical and polarographic techniques[9]. Furthermore, Nilsson and Zettergren demonstrated filling of these primary lesions in the same model using barium sulphate portography[11]. Although this model allows the study of small tumours in the liver, the lesions have not arisen by dissemination. Therefore, it would be inappropriate to draw the same conclusions about portal vascularization in small liver metastases.

Experimental models in which liver metastases are generated by the intravascular injection of single cancer cells have been used for studying metastatic liver disease. Using this transplantation technique in rabbits and mice, Breedis and Young noted minimal filling of liver tumours following portal injection of Indian ink[5]. Similarly, Blanchard *et al.* drew the same conclusion using a radioactive microsphere technique[12] Although the diameter of the experimental lesions in both these studies was not specified, the methodology suggests that they were relatively large

The studies of Ackerman using rat sarcomas implanted directly into liver parenchyma show tumours < 1·0 mm as blank spaces in the liver[7,8]. In some of the 1 0–2·0 mm tumours, predominant filling of vessels with dyes following portal vein injection could be demonstrated. Only when lesions reached 2·0 mm did an arterial circulation seem to be well established. This apparent delay in hepatic artery vascularization (in comparison with our findings) may be artefactual owing to the size of the original tumour implants. Furthermore, the liver trauma associated with direct tumour implantation will result in an inflammatory and healing response which may influence the process of new vessel formation. Our technique of generation of small liver metastases is a better physiological correlate. It is probable that our findings more closely reflect the development of tumour circulation in early disease.

We have shown that metastatic lesions less than 2·0 mm in diameter are more vascular than the surrounding liver parenchyma. Lesions larger than this were on the whole hypovascular by comparison, despite the absence of histological evidence of tumour necrosis. The phenomenon of diminishing tumour vascularity with tumour growth has been well described. This observation has been attributed to progressive hypovascularity of the tumour centre with the maintenance of a hypervascular rim[13]

The clinical relevance of our experimental study is supported by the human post-mortem findings of other investigators. Breedis and Young observed a predominant arterial supply to liver metastases as small as 0·5–1·0 mm in patients who died from disseminated colonic carcinoma[5]. Lin *et al.* noted that portal vein branches often ended abruptly at the tumour periphery, suggesting that these thin-walled vessels had become compressed and obliterated[6].

Our findings have significant implications for the design of clinical trials in adjuvant chemotherapy in gastrointestinal cancer. Regional therapy administered into the portal vein is now being investigated as an adjuvant treatment for colorectal cancer[14,15]. Its aim is to treat metastatic liver disease which is clinically undetectable at the time of surgery. As our study shows minimal internal tumour perfusion by the portal vein, it is likely that this form of treatment will rely on penetration of anticancer agents into tumour tissue from the external vasculature. The size of occult liver metastases may therefore be an important limiting factor in therapy via this route. Patients who appear to be free of liver metastases at the time of surgery may in fact harbour lesions ranging in size from single cells to small metastases a few millimetres in diameter. Our studies indicate that many of these early metastases may already have a well developed arterial blood supply. It follows that chemotherapy via the portal vein will be incompletely effective in preventing the development of liver metastases. However, an improved response to regional chemotherapy might be expected if both the portal vein and hepatic artery were used for drug administration in the adjuvant setting.

Hepatic tumour resection with profound hypothermia and circulatory arrest

D. W. Goh, P. Gornall, K. D. Roberts*, R. Willetts* and M. C. G. Stevens†

*Departments of Paediatric Surgery, *Cardiothoracic Surgery and †Oncology, Birmingham Children's Hospital, Ladywood Middleway, Birmingham B16 8ET, UK*

Correspondence to: Mr D. W. Goh, Hospital for Sick Children, Great Ormond Street, London WC1N 3JH, UK

Major hepatic tumour resection carries high mortality and morbidity rates primarily owing to massive haemorrhage. We have performed a right hepatic lobectomy for hepatocellular carcinoma using profound hypothermia and circulatory arrest. This technique was described by Ein *et al.* in 1981, and enables hepatic resection to be carried out in a bloodless field, thus offering the potential for resection of tumours which would otherwise be deemed unresectable[1]

Case report

An 8-year-old girl presented with abdominal pain, weight loss and gross hepatomegaly. Serum α-fetoprotein was markedly elevated (187 000 units/ml). An isotope liver scan showed irregular hepatomegaly with multiple defects. Abdominal ultrasonography showed large multinodular masses in the right lobe extending to the midline, with compression of the inferior vena cava. A needle biopsy showed a moderately differentiated hepatocellular carcinoma. Chemotherapy was commenced with Adriamycin® (Farmitalia Carlo Erba, St Albans, UK), vincristine, cisplatin and VP-16 (Vepesid®, Bristol–Myers, Slough, UK). The tumour responded to the chemotherapy with progressive falling of the serum α-fetoprotein and decrease in tumour size on ultrasonography. A computerized tomographic (CT) scan 4 months after commencing chemotherapy showed that the tumour in the inferomedial aspects of the right lobe was still large, and was compressing and surrounding the inferior vena cava. Chemotherapy was continued but 9 months after commencing treatment it became apparent that the tumour response had tapered off, and surgical resection was necessary.

A preliminary laparotomy was performed via a transverse upper abdominal incision to assess resectability. The tumour in the right hepatic lobe was large, partially surrounding and closely adherent to the inferior vena cava on its anterior and lateral aspects. The left lobe and porta hepatis were clear. The right hepatic artery, right branch of the portal vein and right hepatic duct were divided.

A median sternotomy was performed and the diaphragm was incised down to the inferior vena cava. After full heparinization, the right atrium was cannulated with a single cannula and the ascending aorta was cannulated. Cardiopulmonary bypass (*Figure 1*) was instituted at a flow rate of 2·4 litre $\text{m}^{-2}\,\text{min}^{-1}$ and a left ventricular vent was inserted. She was cooled down to a nasopharyngeal temperature of 17°C. Cold cardioplegia was used for myocardial protection. The systemic circulation was then stopped and the patient was exsanguinated into the extracorporeal circulation.

During circulatory arrest the tumour was dissected off the vena cava, the hepatic veins were divided and a right lobectomy was performed in a bloodless field. The margin of excision extended right up to the porta hepatis. Visible vessels and ducts were oversewn.

On completion of the resection she was rewarmed to a temperature of 34°C. Bypass was discontinued, decannulation and reversal of heparinization with protamine was carried out. The circulatory arrest time was 48 min.

The sternotomy and diaphragmatic incisions were closed and pericardial and anterior mediastinal drains were inserted. The abdominal incision was closed when satisfactory haemostasis was achieved.

Six hours postoperatively she had a further laparotomy because of abdominal bleeding. A bleeding point on the diaphragmatic suture line was found and controlled with diathermy. There was slight oozing from the raw edge of the liver and this was oversewn with an omental wrap. Subsequent recovery was uneventful.

The histology showed an hepatocellular carcinoma with tumour extending to the excision margin and neoplastic cells within large vascular channels.

Postoperatively she received two courses of VP-16 followed by a course of radiotherapy (2500 cGy) given to the whole volume of the regenerating liver, without complications.

Twenty months postoperatively she remains very well. CT scans and chest radiographs show no evidence of recurrence. Serum α-fetoprotein is undetectable.

Discussion

Major hepatic tumour resections in children are associated with a perioperative mortality rate of more than 11 per cent and a significant morbidity largely attributable to excessive blood loss[2]. Various techniques have been described in efforts to achieve adequate, safe hepatic resection with reduced blood loss. Hepatic resection utilizing normothermic hepatic vascular exclusion is based on the liver's ability to tolerate a warm ischaemia time of up to 1 hour[3]. This technique requires clamping of the abdominal aorta, suprahepatic and infrahepatic vena cava, portal triad, right adrenal vein and phrenic vein, which may prove difficult or impossible with large tumours involving the diaphragm or vena cava. Resection using hepatic vascular isolation and hypothermic perfusion allows a longer ischaemic time of up to 147 min[4]. This technique is not applicable to the smaller child because of the need to cannulate the hepatic artery and portal vein. Resection using normovolaemic haemodilution anaesthesia involves intraoperative removal of the patient's blood and replacement with three times the volume of Ringer's lactate and reinfusing back blood after cessation of major blood loss. Hypothermia of 32°C and hypotension of 40–50 mmHg is maintained[5]. The technique reduces the need for massive intraoperative transfusion. The use of an extracorporeal oxygenator–warmer circuit and roller pump enables rapid transfusion to replace massive blood loss[6]. The two latter techniques do not, however, provide a bloodless field for resection.

The use of profound hypothermia and circulatory arrest to facilitate the removal of abdominal tumours invading the inferior vena cava was first described in 1978 in two children, one with a Wilms' tumour and the other with an adrenocortical carcinoma[7]. Ein *et al.* described a series of six children with malignant hepatic tumours in which resection was performed with cardiopulmonary bypass, profound hypothermia and circulatory arrest[1]. The technique allows an unhurried resection in a bloodless field. In a more recent series the same technique was used in resections of five hepatic and two intravascular Wilms' tumours. The adequacy of the resection margins were determined by immediate frozen sections and in two patients further resections were required[8].

In our patient the preoperative CT scan suggested that the tumour was closely involved with the inferior vena cava and would have been considered unresectable by conventional techniques. The use of cardiopulmonary bypass obviously adds an extra dimension in terms of potential serious complications. However, since adequate resection offers the only means of cure in paediatric liver malignancies[2], the added risks involved can be justified in selected cases if it offers the potential of complete resection. The technique has so far only been used in children. However, in selected circumstances, the technique could conceivably be applied to adults.

Management of pancreatic pseudocysts

R. Andersson, M. Janzon, I. Sundberg and S. Bengmark

Department of Surgery, Lund University, S-22185, Lund, Sweden
Correspondence to;
Dr R. Andersson

Between 1969 and 1987, 68 patients with pancreatic pseudocysts were treated. The median cyst size was 10 cm (range 2–25 cm). Nine patients were managed conservatively with resolution of the pseudocyst occurring in eight patients. These patients had significantly smaller (median 4 cm) cysts compared with those in both percutaneously and surgically treated patients ($P<0\cdot01$). *In 22 patients the pseudocysts (median 9 cm) were punctured percutaneously under ultrasound guidance and the cyst fluid was aspirated or drained through a catheter. Complete resolution occurred in 13 patients after 1–4 (mean 1·8) punctures per patient, regression occurred in six patients after 1–4 (mean 2·0) puncture procedures per patient and three were unchanged. No complications were noted, except that two patients treated percutaneously required additional surgery. Thirty-seven patients were managed surgically (median cyst size 11 cm) with external drainage (12 patients), cystgastrostomy (17 patients), cystduodenostomy (three patients) cystjejunostomy (three patients) and pancreatic resection (two patients). Resolution of the cyst was noted in 29 patients, regression in five and three were unchanged. Five patients required additional surgery. Twelve complications were seen in ten patients (27 per cent), most frequently after external drainage. One patient died after surgical treatment. Mean hospital stay was 13 days among patients treated conservatively and 30 days in both percutaneously and surgically treated patients. Aspiration or catheter drainage of pseudocyst fluid guided by ultrasonography seems a safe and effective treatment of pancreatic pseudocysts and should be considered as initial therapy. If surgery is required cystgastrostomy is preferred.*

Keywords: Pancreatic pseudocyst, surgery, ultrasonography, percutaneous drainage

Treatment of pancreatic pseudocysts has traditionally been surgical[1–4], and surgical management has continued to dominate in the twentieth century[5,6]. However, during the last decade, the introduction and further development of diagnostic techniques such as ultrasonography and computed tomography have improved diagnosis and enabled the development of percutaneous aspiration or drainage of pancreatic cysts[7,8].

The present study was performed in order to evaluate our experience in the management of pancreatic pseudocysts.

Patients and methods

The records of 68 patients with pancreatic pseudocysts treated at the Department of Surgery, Lund University, between 1969 and 1987 were reviewed retrospectively Forty-seven patients (69 per cent) were men and 21 (31 per cent) were women. The mean age was 51 (range 19–95) years The predominant aetiological factor was chronic alcohol abuse (43 per cent), followed by blunt abdominal trauma (16 per cent), biliary tract disease (15 per cent) and cysts seen in association with pancreatic carcinoma (6 per cent) In 14 patients (21 per cent) no definite aetiology could be defined. Abdominal pain was present in 90 per cent of the patients on admission Thirty-two per cent of patients had a history of nausea or vomiting; a palpable mass was present in 12 per cent, weight loss in 10 per cent and jaundice was noted in 9 per cent. The mean serum amylase level was elevated (19·0 (4·0) μkat/l (mean and s.e.m.) normal range 1·2–5·0 μkat/l)

One patient required emergency treatment of the cyst owing to spontaneous rupture The pseudocysts arising after acute pancreatitis (24 patients) were in general initially managed conservatively in order to allow the cyst wall to mature before definitive treatment was decided

Ultrasonography, computed tomography and endoscopic retrograde cholangiopancreatography (ERCP) were introduced during the latter half of the study period, while angiography was used during the first half of the study (*Table 1*) The median cyst size (maximal diameter) in the whole series was 10 cm (range 2–25 cm) Conservative management was followed in nine patients, ultrasonically guided percutaneous needle aspiration or catheter drainage in 22 patients and surgical treatment in 37 patients There were no differences in aetiology or symptoms between the different groups, except that all four patients with underlying pancreatic carcinoma were treated surgically. After the introduction of the percutaneous technique, 47 per cent of patients with pancreatic pseudocysts have been treated with this method and during the last 4 years no patient has been assigned to primary surgery Conservatively managed patients had significantly smaller cysts compared with percutaneously or surgically treated pancreatic pseudocysts ($P<0\cdot01$) The difference in cyst size between patients treated percutaneously or surgically was not significant. In these two groups cysts that were less than 4 cm diameter were seen in patients with multiple cysts

Two or more cysts were seen in one conservatively managed, six percutaneously aspirated and five surgically treated patients Investigation showed communication with the main pancreatic duct in two, four and one patient respectively Cyst fluid was analysed for tumour cells and bacterial growth Tumour cells were found in cyst fluid from two operated patients Positive bacterial cultures were found in four percutaneously and two surgically treated patients

Conservative treatment (nine patients)

The median pseudocyst size was 4 cm (range 2·5–5 cm). Follow-up was with ultrasonography or computed tomography for a median of 5 months (range 1–78 months)

Percutaneous treatment guided by ultrasonography (22 *patients*)

The median cyst size in this group was 9 cm (range 2–15 cm). The site in the epigastrium with the shortest distance to the cyst was chosen, after which puncture was performed under sterile conditions. Eleven

patients had only one puncture procedure, six patients had two and five patients three or four punctures. Aspiration of cyst fluid was performed in 13 patients, in a mean of 1·7 puncture procedures per patient (range 1–4), and drainage through a small indwelling catheter was performed in nine patients, three of whom had an initial aspiration. The catheter was left in the cyst cavity for 1–7 days The mean amount of evacuated cyst fluid was 570 ml (range 10–5000 ml) The patients were then followed up with ultrasonography or computed tomography for a median of 5 months (range 1–18 months)

Surgical treatment (37 *patients*)

These patients had a median cyst size of 11 cm (range 3–25 cm) The surgical treatment consisted of external drainage in 12 patients, cystgastrostomy in 17, cystduodenostomy in three, cystjejunostomy in three and pancreatic resection in two patients. Surgically managed patients were followed up for a median of 6 months (range 1–84 months)

Statistics

Statistical analysis was performed with Fisher's exact test and the Mann–Whitney rank sum test

Results

Conservative management (Table 2)

Conservative management resulted in resolution (i.e complete disappearance) of the pancreatic pseudocysts in eight of nine patients (89 per cent in this group, 12 per cent of the whole series), two of whom had a temporary relapse. No complications were seen.

Ultrasonographically guided percutaneous aspiration or drainage (Table 2)

This was successful in 19 of 22 patients (86 per cent): complete resolution occurred in 13 patients after a mean of 1·8 punctures, and regression (i.e. non-complete disappearance) in six patients after a mean of 2·0 punctures. Two patients required additional surgical treatment (cystgastrostomy and external drainage respectively); in one of these two patients the cyst communicated with the main pancreatic duct. No other complications were noted after the percutaneous procedure. Indwelling drainage catheters were not associated with any side-effects.

Surgical treatment (Table 2)

Surgical treatment resulted in resolution of the pseudocyst in 29 patients and regression in five patients, while the cyst size remained unchanged in three patients. No difference in outcome after surgery could be stated when comparing pseudocysts arising after acute (eight patients) or chronic (11 patients) pancreatitis. Three patients required additional surgery for their pancreatic pseudocysts: two patients had a pancreatic resection, one of which was due to a pancreaticopleural fistula, and the third patient had external drainage. Two patients had gastroenteroanastomosis performed on the second occasion. The complications after surgical treatment are summarized in *Table 3*. Twelve complications occurred in ten patients (27 per cent). The most frequent (seven patients) complication was development of a fistula As can be seen, external drainage was associated with a high complication rate (eight complications in 12 patients; $P<0{\cdot}01$ compared with complications among patients with internal drainage). One patient with alcohol-induced chronic pancreatitis and a pancreatic pseudocyst, who was treated with surgical external drainage, died. He had a reoperation on the fourth postoperative day with a negative laparotomy because of suspected intestinal obstruction, developed a small bowel fistula, deteriorated and died after 2 weeks with multiple organ failure. The mortality rate among operated patients therefore was 2·7 per cent and the hospital mortality rate for the whole series was 1·5 per cent

Hospital stay

The mean hospital stay for conservatively treated patients was 13 days (range 1–40 days) and was 30 days for both percutaneously (range 4–70 days) and surgically (range 5–85 days) treated patients, reflecting the underlying disease and the patients condition rather than the treatment *per se.*

Discussion

Morbidity and mortality following surgical treatment of pancreatic pseudocysts is considerable and postoperative complication rates have been reported to be around 30 per cent[9–11], as in the present study. Our finding that external surgical drainage was associated with a high complication rate (eight out of 12 treated patients) is in accordance with previous work[6,12,13] In our material, internal drainage (in two-thirds performed as a cystgastrostomy) caused significantly fewer postoperative complications ($P<0{\cdot}01$) compared with surgical external drainage. With the advent of non-invasive diagnostic techniques the number of 'diagnostic' exploratory laparotomies soon after an acute pancreatitis attack diminished, an operation often resulting in external surgical drainage of the cyst. This partly explains the high morbidity following external drainage, as acute procedures are associated with a higher morbidity and mortality. Hence, internal and external surgical drainage has not been used in equivalent groups of patients. The outcome after surgery was similar in pseudocysts occurring after acute or chronic pancreatitis as previously reported[14]. In chronic uncomplicated and asymptomatic pseudocysts, a conservative approach is advocated.

Only one patient required acute surgical intervention owing to a cyst complication[15]. Subacute surgical intervention is associated with frequent postoperative complications[6,13,19] Instead, an initial conservative approach allows the cyst wall to mature, giving fewer complications after internal drainage, if surgery is needed[12]. It also allows lesser sac accumulations or intrapancreatic fluid collections to resolve spontaneously[16], leaving the true pancreatic pseudocysts for definitive treatment. Only half of acute 'cysts' will progress to chronic pseudocysts[17] In the present study, eight out of nine pancreatic pseudocysts treated conservatively resolved. Previous reports on successful conservative management emphasize that cysts less than 4 cm in diameter will resolve[11,18,19].

An alternative to surgical internal drainage is percutaneously performed cystgastrostomy with a double pigtail catheter inserted under gastroscopic and ultrasound guidance: it was successful in 19 out of 21 reported patients[20]. Percutaneous puncture or drainage of cyst fluid was successful in 19 of 22 treated patients in our study, while two required additional surgical treatment. Other studies on percutaneous puncture and drainage of pancreatic pseudocysts guided by ultrasonography have also been promising[7,8,21–23], with a high success rate even after a mean follow-up period of 2 years.

In conclusion, small pancreatic pseudocysts seem safe to manage conservatively as they frequently resolve and complications are rare. At least 10 per cent of pseudocysts, probably far more, can be treated thus; in the remaining patients, the cyst wall should be allowed to mature and then should be treated by percutaneous puncture and drainage. In those instances where surgical treatment is needed, internal drainage should be performed if possible.

Extended role for needle biopsy in the management of carcinoma of the breast

Treatment choice in primary breast cancer is wide and still controversial; it seems likely that the optimum treatment for individual patients could be dictated by biological indicators of tumour behaviour. If biopsy could provide prognostic information as well as detailed tissue diagnosis then definitive treatment, with or without adjuvant systemic therapy, could be planned from the outset. We studied 140 patients with a clinical diagnosis of primary breast cancer to determine how much information could be obtained from Tru-Cut® needle biopsies performed at the first clinic visit. Ten patients were found to have benign disease. Of 130 carcinomas, 123 (95 per cent sensitivity) were diagnosed correctly from the needle biopsies, with seven false negative and no false positive results (100 per cent specificity). Precise histopathology was predicted in 121 (93 per cent). Grade was correctly assessed in 77 of 112 (69 per cent), but needle biopsy was not accurate for assessment of lymphatic invasion nor elastosis. Steroid hormone receptors were assayed in 59 needle biopsies, and the incidence of oestrogen receptor positivity (34, 58 per cent) was similar to the resected tumours (35, 59 per cent), but the incidence of progesterone receptor positivity (26, 44 per cent) was lower (33, 56 per cent, P < 0·04). Immunostaining with monoclonal antibody human milk fat globule membrane was accurate in the needle biopsies. DNA analysis by flow cytometry was performed in 37 tumours and the concordance between needle biopsies and resected samples was high. Tru-Cut needle biopsy obviates open biopsy and gives reliable detailed information.

Changes in the understanding of the biology of breast cancer have led to the use of conservation surgery and, in some centres, to the use of systemic treatment before operation[1,2]. It seems likely that optimum treatment for individual patients will be dictated increasingly by biological indicators of tumour behaviour. It is important that a biopsy should provide not only a detailed tissue diagnosis but also as much prognostic information as possible so that definitive treatment, with or without adjuvant systemic therapy, may be planned from the outset.

Early systemic therapy limits the time period during which the tumour can produce mutant clones, some of which may be resistant to endocrine manipulation or cytotoxic agents[3–8]. Theoretically, systemic treatment before operation could produce regression of the tumour to the extent that histopathological grade, receptor status, markers for differentiation and cell kinetics could all be altered or lost. Biopsy of the tumour before any treatment would be the only accurate opportunity for a detailed histological diagnosis and examination of other features.

In cancer of the breast a diagnosis made by histological examination is essential before treatment is started[9–14]. Tru-Cut® (Travenol Laboratories Incorporated, Deerfield, Illinois, USA) needle biopsies for histological examination are quick and simple to carry out, and have been commended for diagnosis in cancer of the breast[9,10,12,15,16]. The aim of this study was to determine how much information of both diagnostic and prognostic value could be obtained from a Tru-Cut needle biopsy, compared with information obtained from the resected tumour taken at definitive operation. Four factors were examined: the histological features of the tumour, oestrogen and progesterone receptors (ER and PR), immunostaining with a monoclonal antibody against human milk fat globule membrane (HMFG-1), and DNA ploidy assessed by flow cytometry

Patients and methods

This prospective study was carried out on patients who presented to the breast clinic at the University Hospital of South Manchester, between 1 April 1984 and 1 April 1986, with a clinical diagnosis of primary operable carcinoma of the breast. Of the 140 patients originally entered, ten proved not to have carcinoma: 130 patients with primary carcinoma of the breast were available for study and their clinical characteristics are shown in *Table 1*. A Tru-Cut needle biopsy was taken when each patient was first seen in the clinic, and the operation was performed a median of 8 days later (range 5–14 days). Either wide local excision followed by radiotherapy (66 patients) or simple mastectomy (64 patients) was performed as deemed appropriate for each patient after consideration of tumour size. After excision a portion of tumour (approximately 70 mg) was stored in liquid nitrogen for estimation of receptors, and the remainder was placed in formalin for histopathology, immunostaining and flow cytometry

The Tru-Cut biopsy technique

Biopsies of tumour were taken after infiltration of the breast with local anaesthetic. Initially a stainless steel pistol was used to take the biopsies with the Tru-Cut needle, but because patients were disconcerted by its use the gun was abandoned after the first 21 biopsies[17].

Several cores were taken from each tumour. The maximum size of a core was $20 \times 1 \times 1$ mm³ Compression (usually 2–4 min) limited bleeding. Patients were advised to take simple analgesics if necessary Two cores were placed in 10 per cent buffered formalin for fixation and subsequent histopathological examination, immunostaining with monoclonal antibodies, and flow cytometry. Two cores were frozen and stored in liquid nitrogen for receptor analysis. Cytology smears were made from these cores for confirmation of malignancy.

0007-1323/89/060553–06$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Histopathology

Sections of all primary tumours were processed routinely by a single pathology laboratory. Tissue was fixed for up to 48 h in buffered formalin, and subsequently embedded in paraffin wax on a tissue processor. Representative blocks were sectioned at 4 μm thickness and stained with haematoxylin and eosin. The slides of Tru-Cut biopsies and surgically removed samples were examined by a single pathologist (L.T.) in a coded and randomized order.

Receptor assays

Fifty-nine pairs of Tru-Cut biopsy specimens and resected samples were assayed for ER and PR by the isoelectric focusing technique, which has been described elsewhere[18,19]. Any positive value with an appropriate isoelectric point was taken to indicate a positive receptor value.

Immunostaining technique for HMFG-1

The monoclonal antibody HMFG-1 was raised in mice as described by Taylor-Papadimitriou and colleagues, and was a gift from them[20]. The details of preparation and immunostaining have been described[21]. At the initial assessment using a microscope at low power, the distribution of tumour cells was examined and any gross variations in staining intensity were noted. Intensity was recorded but, as it is difficult to quantify objectively, it was not used in the final analysis.

Each section had a minimum of 400 tumour cells counted and assessed for the presence of stain. The site of staining was noted as being cytoplasmic, on the cell membrane, or a combination of both. In some tumours staining was found outside the cells in extracellular deposits. This was expressed as the number of deposits seen per high power (400 ×) field. All slides were assessed by one observer (A.D.B.).

DNA ploidy by flow cytometry

Tumours from 37 patients were analysed by flow cytometry. They were selected purely on the basis that the paired tissue blocks were available at the time of this part of the study. Paraffin-embedded, formalin-fixed material was used throughout. Nuclear suspensions for flow cytometry analysis were prepared by the method of Hedley, but with a slight modification of the fluorochrome[22]. Measurements were obtained from a Cytofluorograph Model 4800A (Biophysics System Incorporated, Mahopac, New Jersey, USA) with an argon laser interfaced to a Hewlett-Packard 9845A Desk Top Computer (Hewlett-Packard, UK). Five thousand nuclear particles were measured from each sample.

Half peak coefficient of variability was evaluated for each histogram and ranged from 2 to 10 per cent (median 5 per cent). For the description of aneuploid peaks, DNA indices were calculated as the ratio of the aneuploid peak channel to the first peak that was considered to be diploid or nearly diploid and that was present on each histogram. In multiploid tumours each peak was defined by its own DNA index and the greatest one used for the overall analysis[23]. For calibration of the cytofluorograph, normal human peripheral blood lymphocytes fixed in 95 per cent ethanol and paraffin-embedded tonsils were used. These gave comparable fluorescence for diploid histograms.

*Postmenopausal was defined as a minimum of 2 years since the last menstrual period, values in parentheses are percentages

Statistical analysis

A χ^2 analysis and Fisher's exact test were used for each comparison to relate frequencies of integers between two variables. In accordance with convention $P \leqslant 0·05$ was taken to be significant. Comparisons between two variables recorded as actual numbers (e.g. ER value with staining of extracellular deposits) were made with the Mann–Whitney *U* test, Pearson's correlation and Kendall's non-parametric correlation. Wilcoxon's matched pairs test was used for comparison of the Tru-Cut biopsy with the resected sample when indicated. Eighty variables from each patient were analysed by means of a Hewlett-Packard 9845A desk top computer with a database and statistics program.

Results

Histopathology

Of a total of 140 pairs of Tru-Cut biopsies and resected samples, 130 tumours were malignant. Of these 123 were diagnosed correctly on the Tru-Cut biopsy sample, which gave a sensitivity of 95 per cent. No Tru-Cut biopsy was reported as malignant which subsequently was found to be benign; the specificity therefore was 100 per cent. The accuracy of biopsy did not depend on the size of tumour (*Table 2*).

The definitive histological diagnosis was obtained from 131 (94 per cent) of the Tru-Cut biopsies, and the correlation between the Tru-Cut and definitive surgical pathology was high (*Table 3*). Of the seven tumours incorrectly diagnosed as benign on the needle biopsies, six were found to be infiltrating duct carcinoma and one was an infiltrating lobular carcinoma. Four Tru-Cut biopsies showed intraduct carcinoma only, in two of these this was the final diagnosis, and in two infiltrating duct carcinoma was found in addition. There was adequate tissue on Tru-Cut biopsies to grade 99 of 104 (95 per cent) of the infiltrating duct carcinomas compared with 110 of 112 (98 per cent) in the case of the surgically resected tumours, but the grades of each pair of tumour samples did not always agree. In 77 of 104 (74 per cent) samples the grades were identical, in 14 (13 per cent) the grade was lower in the resected tumour, and in eight (8 per cent) it was higher (*Table 4*), but these differences were not significant.

It was possible to decide on the presence or absence of lymphatic invasion in 103 of 130 (79 per cent) of the Tru-Cut

Table 2 *Size of tumour and accuracy of needle biopsy*

		Tumour size (cm)				
Accuracy of Tru-Cut biopsy	*n*	0·5–1·0	1·1–2·0	2·1–3·0	3·1–5·0	≥5·1
Accurate

	I	II	III	NG
I	9	1		
II	2	41	7	1
III	1	11	26	
NG	2	7	3	1

NG, not possible to grade; no significant differences were found

Table 5 *Oestrogen and progesterone receptor assays: comparison of sample weights and cytosol protein concentrations*

	Sample weight (mg)		Cytosol protein (mg)	
	Tru-Cut biopsy	Resected tumour	Tru-Cut biopsy	Resected tumour
Mean (s.d.)	26·7 (9·3)	67·5 (14·9)	3·3 (2·1)	6·4 (2·6)
Median	25·0	70·0	2·7	6·2
Range	25–30	30–100	0·3–12·3	2·2–14·2

samples, and in 114 of 130 (88 per cent) of the resected tumours. This difference was not significant. Lymphatic invasion was noted in 12 (11 per cent) and in 32 (29 per cent) samples respectively, and this difference was significant ($\chi^2 = 9\cdot03$, $P < 0\cdot002$).

Elastosis could be assessed in 97 (75 per cent) of the Tru-Cut biopsies and 110 (85 per cent) of the resected tumours: 26 (27 per cent) and 41 (37 per cent) respectively of each group demonstrated elastosis, and this difference was significant ($\chi^2 = 4\cdot29$, $P < 0\cdot05$).

Receptor analysis

Reliable receptor analyses were available on 59 of 61 Tru-Cut biopsies (97 per cent); in two (3 per cent) biopsies the results were unreliable because of low concentrations of cytosol protein. The median weight of the resected samples was just more than twice that of the Tru-Cut biopsies, and there were correspondingly higher concentrations of cytosol protein in the resected tumours (*Table 5*)

The proportion of ER-positive tumours was similar in the needle biopsies and resected samples of tumour (58 per cent in Tru-Cut biopsies, 59 per cent in resected tumours). The mean value for ER was greater in the resected tumours than in the Tru-Cut biopsies, but the difference was not significant (*Table 6*).

The proportion of PR-positive tumours was significantly higher in the resected tumours (56 per cent) compared with the Tru-Cut biopsies (44 per cent: $\chi^2 = 4\cdot37$, $P < 0\cdot04$; *Table 6*) The mean concentration of PR in the resected tumours (65·2 fmol/mg cystol protein) was greater than that in the Tru-Cut biopsies (53·1 fmol/mg cystol protein), but this did not achieve significance.

Immunostaining with HMFG-1

Of 130 Tru-Cut biopsies, 121 (93 per cent) contained sufficient malignant tissue for an assessment of HMFG-1 staining (*Table 7*). A sample of 47 sections was assessed on two occasions 3 months apart to determine the degree of discordance in interpretation. In 40 of 47 (86 per cent) the assessment of the percentage of cells stained was within 10 per cent of the value found on the first occasion. In the tumours which had been assessed as positive staining of extracellular deposits on the first reading, all were assessed as positive on the second occasion, but there were minor differences in the number of deposits counted.

The results of immunostaining in the resected tumours were compared with those from the Tru-Cut biopsies by Wilcoxon's paired *t* test and linear regression analysis and significant correlations were obtained. But there was a trend for the percentage of cells which stained to be lower in the Tru-Cut biopsy than in the resected tumour (*Table 7*).

Extracellular staining was more apparent in the resected tumours than in Tru-Cut biopsies. Of the 130 tumours, 21 (16 per cent) were found to have staining of extracellular deposits in the Tru-Cut biopsy specimen, compared with 40 (31 per cent) in the resected tumour ($\chi^2 = 6.94$, $P < 0\cdot01$). Extracellular deposits were recorded in only one Tru-Cut

sample when the definitive tumour did not reveal extracellular staining.

DNA ploidy by flow cytometry

The findings in the resected tumour were essentially similar to those in the Tru-Cut biopsies (*Table 8*). The number of nuclear particles in the G2/M phase or in the second major peak in each Tru-Cut biopsy was compared with the number in that same peak from the analysis of resected tumour. There were some minor differences. One diploid tumour was tetraploid in the second sample (taken as 'G2/M' > 10 per cent of total cell population), and there were minor changes in 'other DNA-aneuploid' tumours. When tetraploid tumours were considered, there were apparent differences between the Tru-Cut biopsies and the resected tumours. In six tumours the number of particles in the tetraploid peak was greater, in four it was lower, and in five it was the same. These differences failed to achieve statistical significance.

Discussion

Optimum treatment for carcinoma of the breast is still the subject of considerable debate. Although there has been a trend towards minimal surgery it is by no means clear that this is the treatment of choice for all patients; neither is it certain which patients should receive systemic treatment as part of initial management of the primary disease. It seems likely that as molecular biology is used to develop probes and immunology to develop tumour markers, it will become apparent that the treatment of choice for individual patients may need to be tailored to each specific type and prognostic group of tumour. The need to define precise pathology and predict the likely behaviour of a tumour before definitive treatment is planned is therefore of increasing importance.

Open biopsy, with or without frozen section examination, is inefficient in terms of time taken by surgeons, anaesthetists and pathologists[9,24,25], and it may require admission and general anaesthesia. An alternative is to take a small sample of tumour in the outpatient clinic with a drill or needle. High speed air drills produce good cores of tissue which result in high diagnostic accuracy and no false-positive results, but the equipment is cumbersome and the noise of operation disturbing to patients[26,27].

Fine needle aspiration and cytological examination has been used extensively[28]. It is cheap, easy to perform and virtually free from complications[29]. Unfortunately false positive results occur[10,15,30–33]. In particular there are difficulties in the interpretation of cells from some benign proliferative disorders[11]. Other studies confirm the significant false positive rate that can occur with cytology alone[34–37].

The advantages of Tru-Cut biopsy for the patient with operable disease are clear; it has high sensitivity, it is accurate in assessing pathology, and considerable information may be obtained in addition to a simple diagnosis. The sensitivity of the technique was 95 per cent. This compares favourably with results reported by previous workers who found sensitivities of 89 per cent[12], 80 per cent[16], 79 per cent[32], 67 per cent[9], 74 per cent[10] and 79 per cent[33]. There was no false positive result either in this study or in previous studies. Tru-Cut needle biopsy did not provide sufficient tissue for accurate assessment of lymphatic or vascular invasion or elastosis, and both were underestimated, but these factors are relatively unimportant in the prediction of prognosis. This suggests that there is not a sufficiently representative sample to compensate for tumour heterogeneity for these factors.

The Tru-Cut biopsy provided adequate tissue for receptor estimations by isoelectric focusing and the percentages of ER-positive and PR-positive tumours were consistent with those in other reported series[38–45]. The proportion of tumours which were PR positive in the resected specimens was significantly greater than that in the needle biopsies. This may be a reflection of heterogeneity of the tumours, or of technical difficulties in the assay when applied to small needle biopsy specimens. Receptor status has been reported to vary in different parts of the same tumour[46–49], and it seems inevitable that receptors will be found more easily in relatively large samples. The sensitivity of the isoelectric focusing technique depends on the total cytosol protein in the tissue[19]. Consistently lower protein concentrations were found in the Tru-Cut biopsies than in the resected tumours.

The results of this study indicate that ER and PR concentrations can be measured on needle biopsies: it should be possible to determine responsiveness more accurately by the use of needle biopsies both before and after tamoxifen[50]. The availability of monoclonal antibodies to ERs and PRs is likely to facilitate receptor estimations considerably.

Human milk is rich in antigens normally associated with the cell surface, and it provides an excellent medium for the production of antibodies to these constituents. The antibody HMFG-1 identifies antigens found on the milk fat globule membrane, and those present on the surface of normal mammary epithelium and within the ducts[21,51–53]. Mammary carcinomas express these antigens on the cell membrane, in the cytoplasm, and sometimes extracellularly. The pattern and intensity of staining varies greatly between one tumour and another and sometimes within different areas of the same tumour[53]. This makes objective assessment difficult. Various methods of assessment, including scoring systems, have been used, and prognostic information has resulted[21,52,54–56]. Only six of 130 (5 per cent) Tru-Cut samples provided insufficient material for HMFG-1 assessment. From the majority of Tru-Cut biopsies, the percentage of cells stained was an accurate reflection of the resected tumour. The Tru-Cut biopsy samples were adequate for the assessment of cell membrane staining but they were not adequate for the assessment of extracellular stain. This failure to detect extracellular deposits was significant.

Flow cytometry is a rapid and reproducible technique for determination of the DNA content of cells. The introduction of a method whereby paraffin-embedded tumours may be used for flow cytometric analysis has led to the examination of archival material, and a means by which cellular DNA content can be related to subsequent response to treatment, survival and a variety of other factors[22,23,57–59]. In one study aneuploid tumours recurred more rapidly than diploid tumours[60], and survival of patients after relapse may be related to DNA ploidy[61]. Aneuploidy has been associated with lymph node metastases[62], but others have failed to confirm the relationship[63,64]. Tru-Cut biopsy samples provided adequate tissue for DNA ploidy analysis by flow cytometry and it was not difficult to obtain 5000 nuclear particles after dissociation of the tissue. Histograms were consistent with those from resected tumours. In previous studies variations in DNA ploidy were not found between primary tumours and axillary metastases[58,64], were found rarely when multiple biopsies were taken in one study[65], and in another study they were found in two of eight tumours[66].

In summary in this study we found that it was possible to obtain almost as much information concerning a tumour from the needle biopsy as from the resected tumour. The advantages of Tru-Cut needle biopsy for the patient with operable disease are clear. It can be performed in the clinic at the first visit with the minimum of disturbance for the patient, and requires no specialized equipment or staff. What is important, and what cannot be quantified, is the experience of the individual who takes the biopsy and the experience of the histopathologist who interprets the tissue. A recent study found that needle biopsy or aspiration cytology is used to make the initial diagnosis in only 2–10 per cent of all new breast cancer cases[67]. One possible reason for the reluctance of clinicians to use needle biopsy techniques is the worry that malignant cells may be disseminated by the insertion of the Tru-Cut needle If this actually does occur, it does not seem to influence survival any differently from excision biopsy[68]. This study confirms and extends the value of Tru-Cut needle biopsy in the management of cancer of the breast.

Mr H. White

An analysis was carried out of 43 patients treated by omental transposition for locoregional problems associated with breast cancer. Indications for surgery included advanced primary tumour (five), locally recurrent tumour (32), radiation induced sarcoma (two), and radionecrosis (four). Tumours were typically extensive (mean diameter 7·2 cm) and skin ulceration affected 30 patients. Other treatment modalities had been exhausted. Surgical excision followed by reconstruction using transposed omentum resulted in worthwhile local control and symptom relief in 31 patients (median duration 22 months). Chest wall disease rapidly recurred peripheral to the omental graft in 12 patients. On multiple regression analysis, duration of local control was significantly related to tumour diameter, ulceration, and earlier radioresistance (hazard ratios 15·8, 3·8 and 14·8 respectively). Survival (median 21, range from 1·5 to 122 months) correlated with tumour size, previous chemotherapy, and early re-recurrence (hazard ratios 7·2, 3·0 and 4·3). Omental transfer is a reliable method of restoring epithelial cover after radical surgery and is particularly useful after previous irradiation injury. In advanced and recurrent breast cancer, an aggressive surgical approach significantly improved the quality of life of most patients, but careful case selection is required to avoid inappropriate surgery for irremediable tumours.

Keywords: Omentum, breast neoplasms, radiation injuries, prognosis, local recurrence, survival

Despite changing public awareness, a number of women continue to present with locally advanced breast cancer Extensive locoregional recurrence occurs occasionally in the absence of overt distant metastases. Both may prove resistant to non-operative treatment: relentless tumour growth results in ulceration of overlying skin and secondary infection. Initial distress is compounded by that associated with a fungating and malodorous tumour mass.

Primary breast cancer is now commonly treated by a combination of local tumour excision and irradiation. Problems that may follow radical radiotherapy include tumour recurrence in the irradiated breast, radionecrosis and radiation-induced sarcoma.

While surgery for limited primary disease has become more conservative, attitudes to chest wall recurrence have also changed. Radical excision followed by reconstruction using myocutaneous flaps has become accepted practice in a number of centres[1]. However, poor vascularity in irradiated tissues, necrosis, and uncontrolled secondary infection may all be obstacles to wound healing. In such circumstances, the technique of omental transposition may offer advantages[2]. Transferred on a reliable vascular pedicle, greater omentum can be readily moulded to fit the extensive irregular crater that adequate cancer clearance creates. When required, it can be placed over synthetic mesh following full-thickness thoracic wall resection. The profuse granulation tissue which rapidly appears on the surface of exposed omentum provides an excellent base for skin grafting[3,4].

This report summarizes the results of omental transposition, the preferred technique of one surgeon (H.W.), undertaken in 43 patients for difficult problems relating to breast cancer and its treatment.

Patients and methods

Between the years 1977 and 1987, 43 women underwent omental transposition for breast cancer and related chest wall problems Mean age was 54 years (range 30–80 years). The indications for surgery were advanced primary breast cancer (five), recurrent breast cancer (32), radiation induced sarcoma (two), and radionecrosis (four)

Many patients had relatively slowly progressing tumours, and the interval between the initial diagnosis of cancer and omental transposition ranged from 14 months to 22 years (mean 72 months). Local disease was for the most part extensive. tumour diameter varied between 2 and 25 cm (mean 7·2 cm). In 30 patients with skin breakdown, ulceration had been present for up to 3 years (mean 13 months) Satellite cutaneous deposits of tumour were visible peripheral to the main lesion in 14 patients, and in three there was tumour in the contralateral breast Enlarged lymph nodes were palpable in ten patients, and six were known to have distant metastases at the time of surgery

Patients were typically referred for salvage surgery by colleagues in radiotherapy and oncology only after exhaustion of other therapeutic modalities All patients had at some time been irradiated, and 11 (26 per cent) received multiple courses to the breast and/or chest wall In 18, radiotherapy (mean 58 Gy, range 40–65 Gy) was given without tumour excision: 15 of this group presented with locally advanced primaries. Twenty-one patients had previously received cytotoxic chemotherapy (in two this was adjuvant to initial surgery). Thirty-six patients experienced one or more forms of endocrine manipulation. Assessable responses to earlier non-surgical treatments are shown in *Table 1*.

Preoperative assessment

The technical aspects of omental transposition to the chest wall are described and illustrated in detail elsewhere[4,5]

Briefly, extensive peritoneal adhesions or previous gastric or colonic resection were regarded as contraindications to attempting omental transfer Up-to-date assessment of the extent of malignant disease was considered essential Diagnosis was established by preoperative needle aspiration cytology or Tru-cut* (Travenol Laboratories Incorporated, Deerfield, Illinois, USA) biopsy Where appropriate, computerized tomographic scanning was used to estimate the depth of chest wall infiltration While age itself was not a contraindication,

respiratory function tests were performed where surgical clearance might necessitate resection of one or more ribs or sternum.

Patients were given a detailed explanation of the likely postoperative course of events and possible complications It was emphasized that intended surgery was for control of local symptoms, and the procedure should not necessarily be regarded as curative.

Surgical technique

A plastic drape was used as a flap to separate the contaminated breast region from the abdominal operative field and the abdomen was explored through an upper midline incision. Abdominal access was used to remove both ovaries in five premenopausal women. Hepatic metastases were considered a contraindication to proceeding further in one patient

The omentum was first detached from the transverse colon along the embryological line of fusion and then freed from the greater curvature of stomach. Gastric branches of the gastroepiploic vessels were individually ligated, taking care not to occlude the gastroepiploic arcade itself. Absorbable ligatures were always applied to the omentum After careful assessment of the vascular contribution of each, either the left or the right gastroepiploic pedicle was divided at its origin. A right sided pedicle supplied the graft in 30 patients, while the left vessels were used on 13 occasions. Although a separate subcostal incision was used initially in this series, subsequently, the mobilized omentum was brought out of the abdomen through the upper part of the laparotomy wound. Care was taken to avoid torsion or traction of the vascular pedicle.

Every effort was made to excise all grossly neoplastic and infected tissue with at least a 2 cm margin. Surgery included mastectomy in 25 patients, underlying muscle was excised in 19, and a part of the thoracic cage was resected in eight. Attempted 'curative' resection in one patient involved a forequarter amputation. The omentum was tunnelled subcutaneously and sutured to the margins of the surgical defect. Both the tunnel and the exit from the abdomen were of sufficient width to avoid compression of the omental pedicle, even at the risk of a subsequent incisional hernia The chest wall was stabilized and intrathoracic structures protected by inserting prosthetic mesh (Marlex®, C.R Bard Incorporated, Massachusetts, USA) deep to the transposed omentum in six patients To allow for the development of granulation tissue and possible appearance of areas of partial necrosis, skin grafting was initially delayed for 10 to 14 days A 1.3 meshed split-thickness graft is now applied immediately, thereby considerably shortening inpatient stay.

When possible, patients were followed up at 3-monthly intervals after discharge from hospital Mortality, additional treatment and timing and distribution of further malignant disease were documented.

Analysis

Results were compiled retrospectively using the Clinical Research System at the Royal Marsden Hospital. Kaplan–Meier type curves of local control and survival after omental transposition were constructed The prognostic significance of each of a number of preoperative and operative factors was analysed using the log rank test (see results). To assess the importance of these factors independent of one another, Cox's multiple regression analyses were performed^6

Results

Restoration of epithelial cover was achieved in 39 patients. Duration of hospital inpatient stay ranged from 11 to 66 days, with a mean of 33 days.

Complications

Most of the complications affecting the omental flap were temporary and easily corrected (*Table 2*) Omental haematoma and venous thrombosis occasionally resulted in partial graft necrosis: this was easily débrided One patient was excluded from this series as intended omental transposition had to be abandoned when the left gastroepiploic vessels proved to be inadequate, resulting in total graft necrosis; transfer in subsequent cases was always based on a right sided pedicle. A devascularization injury to the transverse colon was the result of technical error in failing to recognize the plane separating the omentum and mesocolon. Segmental resection with primary colonic anastomosis was performed without further complication. Two patients later required repair of their subcostal hernias. No subsequent problem relating to intra-abdominal sepsis or adhesions was experienced. After chest wall excision and mesh repair, respiratory embarrassment was transient.

Lymphoedema of the upper limb was present at the outset in nine patients. This deteriorated in three cases and developed *de novo* in a further four. No improvement in swelling was seen as a result of omental transposition.

Local control

Removal of the main source of symptoms gave worthwhile palliation in 31 patients (median duration 22 months, range 2·5 months–10 years). Surgical reconstruction proved successful in the four patients treated for radionecrosis and none developed recurrent ulceration.

Omental transposition was combined with tumour excision in 39 patients. Further local recurrence occurred in skin surrounding the omental graft in 23 of these, and went on to involve the omentum in 13 Tumour confined to the transposed omentum was seen only twice. Recurrent chest wall disease again led to symptoms in 15 patients. Surgery had been of little or no benefit in 12 of this symptomatic group as the further recurrence became apparent within 2 months (*Figure 1*).

HR, hazard ratio, values in parenthesis are 95% confidence intervals

Local control was significantly shorter in patients with the following six features (*Table 3*): bigger tumours, particularly those in which the diameter exceeded 10 cm (*Figure 2*), ulceration (*Figure 3*), satellite cutaneous deposits, palpable lymph nodes, previous resistance to radiotherapy and a cancer history of less than 3 years. On multiple regression analysis, the variables which had independent influence were tumour diameter greater than 10 cm, ulceration, and radioresistance; the time interval between breast cancer diagnosis and omental transposition was of borderline importance (hazard ratios 15·8, 3·8, 14·8 and 2·2 respectively; *Table 4*).

Primary tumour grade and oestrogen receptor level were not available in most cases There was no significant association between local control and age, menopausal status, primary tumour size, response to endocrine therapy, known distant metastases, the extent of chest wall resection or histological confirmation of tumour clearance. However, detailed information on microscopic clearance at resection margins was available for only 20 of the 39 patients: 'complete' excision in 12, margin involvement in eight.

Survival

Overall survival after omental transposition ranged from 6 weeks to 10 years, median 21 months (*Figure 4*). Nineteen patients are alive at the time of writing, but only eight are free

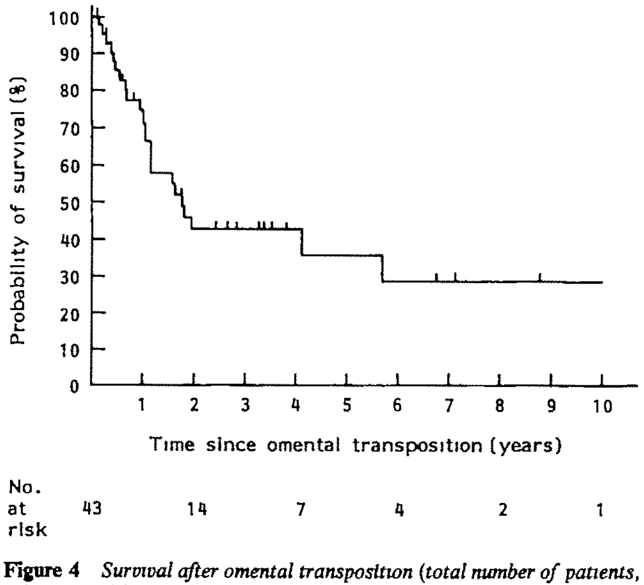

Figure 4 *Survival after omental transposition (total number of patients, 43). Vertical bars indicate duration of follow-up*

of malignant disease. Prognosis was closely related to tumour diameter, as measured in the resected specimen (*Figure 5*) Median survival was only 12 months in patients who had previously received cytotoxic chemotherapy (*Figure 6*) These factors were independent of one another on multiple regression analysis (hazard ratios 7·2 and 3·0 respectively; *Table 4*). Survival was further shortened in the patients who developed early local recurrence (hazard ratio 4 3).

Deaths have all been the result of either locally advanced or metastatic malignant disease Five of six patients who had disseminated breast cancer at the time of surgery together with four additional patients succumbed to distant metastases. Two patients had both metastases and extensive chest wall disease at the time of death In the patients who developed early recurrence, all ten deaths were related to breast cancer involvement of the chest and chest wall. Three further patients died of disease mainly confined to the thoracic region

Discussion

Most patients who develop locally advanced breast cancer or recurrence after mastectomy have associated distant metastases or develop them within a relatively short time Breast cancers are usually radiosensitive and aggressive radiotherapy is probably the treatment of choice[7]. Many cases then succumb to metastatic disease before their local disease again becomes apparent or troublesome. The reported incidence of further recurrence after radiotherapy ranges from 32 to 65 per cent[7–11]. Earlier treatment usually precludes the use of additional external beam irradiation within the same field, although a radioactive implant can occasionally be considered While responses to endocrine therapy are generally superior both in quality and duration to those obtained from cytotoxic chemotherapy[12], only a minority of breast cancers respond to hormonal manipulation and duration of relief may still be short It was in this 'last resort' context that the patients in this series were referred for consideration of palliative radical surgery

Many of the factors known to influence prognosis in primary breast cancer have little bearing on local control or survival after relapse[8] Previous reports have demonstrated that prognosis is unaffected by age, menopausal status, primary tumour stage or initial surgery (incisional or excisional)[9,13]. However, clinical estimation of a tumour's growth rate and biological markers of growth aggressiveness (e.g histological grade and oestrogen receptor status), can provide useful and independent prognostic information[14,15]. Life expectancy after local recurrence generally correlates with the length of the disease-free interval after mastectomy[7–9,11,16]. Both the size and number of sites of local recurrence give an indication of prognosis[8,13].

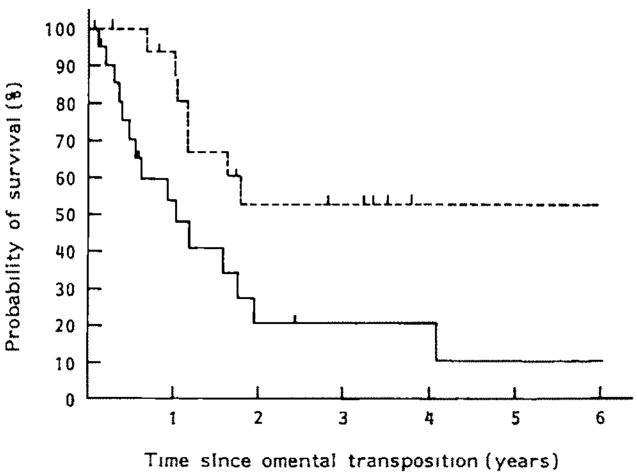
In this series, local control and survival were closely related to tumour diameter. Tumours greater than 10 cm were associated with a particularly poor prognosis. While the area of skin breakdown was partly related to tumour size, ulceration had an additional and independent adverse effect on subsequent local control Satellite cutaneous deposits and lymph node enlargement both predisposed to further chest wall recurrence. Duration of local control was significantly shorter in patients in whom breast cancer had first been diagnosed within the 3 years preceding omental transposition. Somewhat surprisingly, survival was not influenced by the length of this interval.

Radioresistance is a further indication of tumour aggressiveness. Danoff *et al* reported a 62 per cent 3-year survival rate in 40 patients with isolated local recurrences which completely responded to radiotherapy, compared with zero in non-responders[9]. In 52 cases treated by chest wall resection for recurrent breast cancer, Shah and Urban found that earlier radioresistance reduced 5-year survival from 57 to 19 per cent[17]. Our findings are in agreement, in that both local control and survival were very short in three patients whose disease progressed during radiotherapy. The effect of radioresistance on local control was significant and independent of other adverse risk factors.

Life expectancy was significantly reduced in patients previously treated by chemotherapy. This association was independent of the other factors investigated and first became evident some 2 years after omental transposition. The chemotherapy group included both non-responders and those with disease relapse after an initial response to cytotoxic treatment. While this apparent effect may be spurious, Powles *et al*, in a study of combination chemotherapy for advanced breast cancer, reported shorter survival in those who survived beyond 1 year after first relapse[18].

The indications for this type of radical surgery are typically pain and ulceration where life-expectancy can reasonably be expected to exceed 12 months[2]. Palliative surgery should not necessarily be dismissed in patients with distant metastases For 2 years after omental transfer, survival in the small number of patients with known disseminated disease differed little from the remainder, suggesting that we selected patients with relatively slow growing metastases.

The difficulty that may be experienced in controlling or



No. —— 18	15	7	6	2	2	2

risk						

Figure 6 *Survival related to previous cytotoxic chemotherapy (total number of patients, 39),* - - - - - *no chemotherapy (18),* ——— *earlier chemotherapy (21),* P<0 025. *Vertical bars indicate duration of follow-up*

palliating local recurrence emphasizes the importance of optimal treatment to 'high risk' primary breast tumours. In 42 per cent of the patients described, primary cancers were treated with radiotherapy alone Although the probability of local control is widely held to be dose-related, only two of this group received less than 60 Gy. Hence, subsequent failure could not in most cases be attributed to inadequate irradiation. Combining radiotherapy with tumour excision or interstitial implantation of the primary site has been reported to improve control of local disease[19]. While not questioning the rationale of avoiding misplaced surgery in initially 'inoperable' disease, close follow-up is essential to permit early 'salvage' surgery should this become necessary

The list of complications appears extensive but most were of a relatively minor nature. If compression of the omental pedicle in the subcutaneous tunnel is to be avoided, abdominal wall hernias are inevitable in some patients. Separate subcostal incisions are no longer used, as any herniation at the upper end of a mid-line incision overlies the liver and generally presents less of a problem. Where necessary, the omental pedicle can usually be divided after about 3 months and the hernia repaired[20]. However, if extensive radiotherapy has altered the normal development of collateral vascular connections, viability should first be tested by carefully cross-clamping the gastro-epiploic supply[21]. Upper limb lymphoedema was unaffected or occasionally deteriorated, a finding in agreement with other reported results[22].

Greater omentum has immunological and angiogenic properties that confer a healing capability when it adheres to inflamed and damaged surfaces within the peritoneal cavity. Transferred to an infected irradiated site, the scavenging capabilities of omental macrophages together with a dense surface capillary network promote epithelialization and skin graft survival[4]. In general, the objective of omental transposition was the removal of a troublesome malodorous ulcer and not necessarily eradication of malignant disease. In this light, the procedure resulted in symptom relief for an appreciable period and could be judged worthwhile in the majority of patients.

Experience with limited radiotherapy suggests that even apparently small local recurrences are typically an indication of more extensive chest wall disease[11]. Breast cancer commonly permeates through intercostal lymphatic channels into sub-pleural tissues[23] and tumour cells were probably present peripheral to resection in many of the cases presented. While most patients enjoyed a markedly better quality of life, 12 patients developed early recurrence peripheral to the omental graft. This was thought to reflect the biologically aggressive nature of their disease and none survived beyond 2 years after surgery. Very large tumours with diameters greater than 10 cm are probably beyond salvage by this or any other method.

Acknowledgements

We are grateful to Professor G Westbury of The Royal Marsden Hospital and Professor A. J. S. Davies of The Institute of Cancer Research for their helpful suggestions. We would also like to thank the anaesthetists, pathologists, theatre staff and surgical registrars of the hospital for their assistance and interest in this work, and the physicians, radiotherapists and surgeons who referred patients to us.

Thirty eight ductal carcinomas in situ *of the female breast detected during the first 7 years of screening by the Guildford Breast Screening Unit have been treated by one surgeon. Twenty-eight cases were treated conservatively and ten by mastectomy. In the group treated conservatively there have been five local recurrences: four as ductal carcinoma* in situ *and one as node negative microinvasive carcinoma. There were no clinical or pathological features that predicted local recurrence, which was detected only by follow-up mammography. Based on these early results, an initially conservative approach to screen detected ductal carcinoma* in situ *is advocated.*

Keywords: Ductal carcinoma *in situ*, breast cancer screening, mammography, local recurrence

Ductal carcinoma *in situ* of the female breast progresses to invasive carcinoma in an unknown proportion of cases and after an unknown time interval; this lack of precise knowledge concerning its natural history has resulted in controversy surrounding the choice of surgical procedure[1]. Conservative surgical operative treatment is favoured by some[2] while others adopt a more radical approach[3]. Retrospective studies based on an initial incorrect diagnosis of benign lesions[4,5] at biopsy have shown that in a proportion of patients with ductal carcinoma *in situ* (up to 40 per cent) there is a transformation to invasive carcinoma. There are no histological features which enable the pathologist to predict invasive transformation of an *in situ* carcinoma[4,5] and this has resulted in an empirical approach to treatment.

Ductal carcinoma *in situ* is detected more frequently after the introduction of screening using mammography[6] and poses a considerable management problem to clinicians involved in treating screened populations. The objective of this paper is to report the results of the treatment of a series of ductal carcinomas *in situ* detected during the first 7 years of the Guildford Breast Screening Programme.

Patients and methods

Women between the ages of 45 and 69 years were enrolled in the Guildford Breast Screening Programme from general practices in Guildford from 1979, and offered screening three times by mammography with clinical examination at 2-yearly intervals and clinical examination alone in intervening years Women with suspected breast lesions are examined and where appropriate fine needle aspiration cytology is performed with ultrasound guidance where necessary All suspicious abnormalities are excised after preliminary localization using the dye contrast method, this is followed by specimen radiology to assess the completeness of resection.

Treatment

Operative procedure is determined by the probable size and position of the lesion and its relationship with the central core of the breast assessed mammographically Small lesions are removed by local or segmental excision and larger lesions by quadrant excision usually with axillary and/or second intercostal space lymph gland sampling and biopsy of the ducts of the central core of the breast[7].

All surgical specimens are examined by one histopathologist using a large section technique and chemical clearance of axillary tissues as an aid to the detection of all axillary lymph glands[6] Further treatment is dependent on the histological report and the results of postoperative mammography at follow-up. Patients with apparent multiquadrant disease and some with diffuse (multifocal) *in situ* ductal carcinoma have been treated by mastectomy Of the 38 patients, four have been treated by radical subcutaneous mastectomy, six by Patey mastectomy and 28 by local excision. Of those managed conservatively, five received quadrant excision and 23 segmental excision. After treatment women are followed up with 6-monthly recall and annual mammographic assessment. The follow-up is complete after a mean of 42 months. The group treated by local excision has a mean follow-up of 38 months and the mastectomy group 55 months, all groups have been followed for between 6 and 84 months

Multicentric, diffuse and focal in situ *carcinoma.* Multicentricity is defined for the purposes of this investigation as multiple malignancies that are not interconnected through the duct system. This criterion can only be determined in mastectomy excisions when different quadrants show malignancy, although the central core ducts are free of disease Multicentricity in limited excisions cannot be proved as all the lesions may be interconnected. *In situ* carcinoma in limited resections was therefore subdivided into diffuse, where the entire duct system was involved, or focal, where isolated ducts showed malignancy although those intervening were normal.

Statistics

Inter-relationships between pathological and clinical characteristics were determined using the Mann–Whitney U test and the χ^2 test employing Yates' correction. Kaplan–Meier life-table analysis was used to calculate the local recurrence rate.

Results

Diagnosis

Thirty eight cases of *in situ* ductal carcinoma without invasive carcinoma were detected by mammography. Malignant cells were found by fine needle aspiration cytology in seven of 20 attempted aspirations

Clinical characteristics

The mean age of the group was 56 years, although the mean age of those who had local excision (54 years) was less than those who had mastectomy (57 years), this was not significantly different

Twenty (53 per cent) patients were premenopausal and 18 (47 per cent) postmenopausal. There were no significant differences between the menopausal status of the treatment groups (*Table 1*).

Site

The majority of ductal carcinoma *in situ* was found in the upper outer quadrants of the breast (*Figure 1*); this is in accordance with the volume distribution of breast tissue by quadrants.

Tumour size

The size of tumours varied between 4 and 55 mm with a mean size of 21 mm. Distribution of tumour size is shown in *Figure 2*. Ductal carcinomas *in situ* treated by mastectomy had a mean diameter of 34 mm which was significantly larger than in

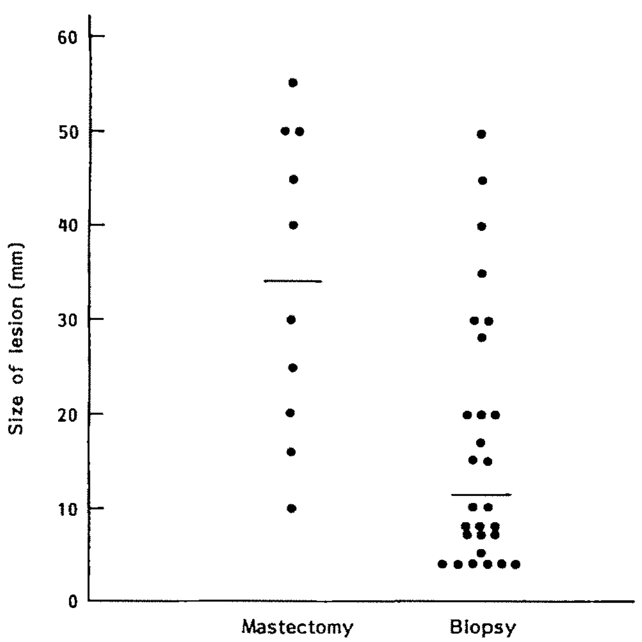

Figure 2 *Size of lesions treated by mastectomy (mean = 34 mm) and biopsy (mean = 16 mm) Mann–Whitney* U *test* z = 2·95, P < 0·01

patients who were treated by excision biopsy, where the mean diameter was 16 mm ($z = 2.95$, $P < 0.01$, Mann–Whitney *U* test).

Multicentric, diffuse and focal lesions

Seven of the ten mastectomies showed either multicentric *in situ* carcinoma or diffuse involvement of one quadrant, and six showed residual ductal carcinoma *in situ* after apparently complete excision biopsy. Diffuse *in situ* carcinoma was found in 12 of the 28 cases of quadrant resection, and focal disease was found in the remainder. Diffuse lesions were significantly larger than focal lesions with a mean diameter of 14 mm ($z = 2.69$, $P < 0.01$, *Figure 3*). All lesions larger than 40 mm were multifocal.

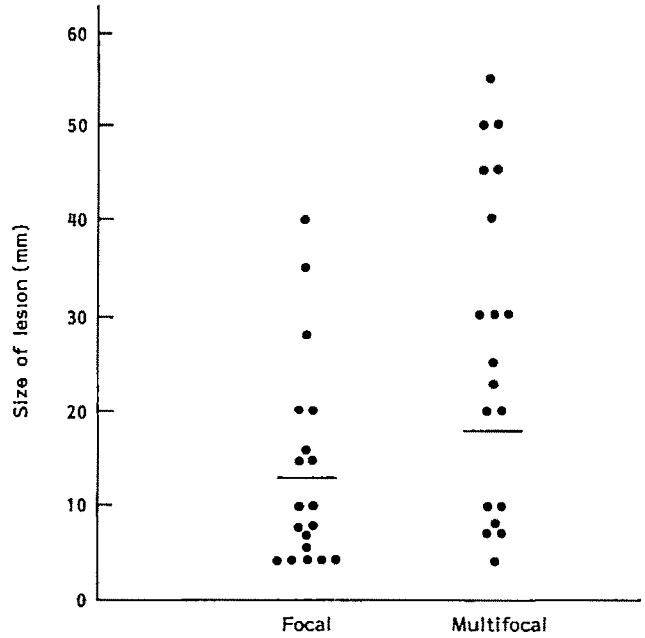

Figure 3 *Size of focal (mean = 14 mm) and multifocal (mean = 28 mm) lesions. Mann–Whitney* U *test·* z = 2.69, P < 0·01

Recurrent disease

All recurrences were detected when mammographic abnormalities (microcalcification) were found at examination which took place at intervals of 6–12 months There were five local recurrences at a mean period of 18 months, with cumulative freedom from recurrence of 77 per cent (life-table analysis, *Figure 4*) at 7 years. Four had been treated with local excision and one by excision followed by radiotherapy. The recurrence in the latter patient showed a microinvasive carcinoma without lymph gland metastases at subsequent Patey mastectomy. The single case of invasive cancer results in an 8 per cent actuarial progression to invasive carcinoma rate over a 7-year period (Kaplan–Meier life-table analysis).

Comparison of recurrent and non-recurrent cases

The mean age of those with recurrence was 57 years, the same as the mean for the non-recurrent group. There was no significant difference between the proportion of premenopausal women in the recurrent (40 per cent) and non-recurrent (48 per cent) groups.

The mean size of the original lesion in those with recurrence (16 mm) was not significantly different from that in patients with no recurrence (19 mm; *Figure 5*). Although all recurrences occurred in the same area of the breast as the original ductal carcinoma *in situ*, the size of the surgical excision specimen (as

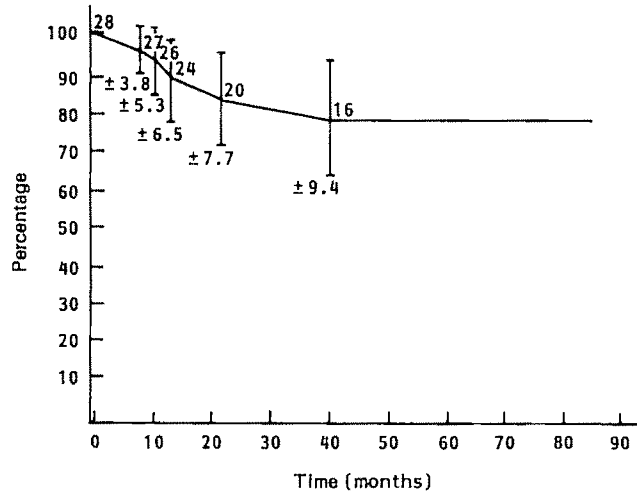

Figure 4 *A life table illustrating the cumulative freedom from recurrence following local resection of screen detected ductal carcinoma* in situ. *The bars show the standard error*

opposed to the lesion itself) in patients who remain disease free (mean 27 cm^2) was not significantly different from the resection specimens in patients who developed recurrent disease (mean 30 cm^2).

Similarly, whether or not the lesion was focal was not related to recurrence; two recurrent cases were originally diffuse and three focal compared with ten multifocal cases remaining in the non-recurrent group of 23 women ($\chi^2 = 0{\cdot}13$, $P > 0{\cdot}5$).

Treatment of recurrent cases

The five instances of recurrent disease were treated by further surgical excision. Two were treated by wide local excision, one by subcutaneous mastectomy, one by quadrant mastectomy with axillary clearance, and one by Patey mastectomy; all remain disease free at a mean time of 22 months (range 6–36 months) since treatment for recurrence.

Discussion

The nearest approximation to the natural history of ductal carcinoma *in situ* comes from retrospective studies where biopsies previously thought to be benign were found to contain ductal carcinoma *in situ*[4,5] Follow-up of these women who received only excision biopsy has shown that up to 40 per cent will progress to invasive cancer in the same breast over 10–15 years. In contrast, small series where symptomatic ductal carcinoma *in situ* has been managed conservatively[8,9] have shown an unacceptable recurrence rate and progression to invasive carcinoma. The introduction of mammography has enabled asymptomatic cases of ductal carcinoma *in situ* to be detected, and in screened populations these lesions comprise 15 per cent of all detected carcinomas[6]; by comparison, symptomatic ductal carcinoma *in situ* is a rare event[2]. There is no precedence for treating screen detected carcinomas as previous studies have been concerned mainly with symptomatic patients[2,8–10] whose disease may show a more aggressive biological behaviour. Lagios *et al*[11] in a selected group of women with mammographically detected lesions <8 mm in diameter has shown a recurrence rate of 15 per cent at a mean follow-up time of 44 months after local excision only. In a further study[12], size has also been used to advise management by lumpectomy and radiotherapy rather than by mastectomy In this study of 51 women, with a mean size of ductal carcinoma *in situ* of 1·4 cm, there was one recurrence but with a short mean follow-up time of 27 months. A conservative approach to screen detected lesions may thus be justified; however, *in situ* carcinoma is a malignancy curable by surgery and so it is perhaps a paradox that cure might be prejudiced by conservative surgery

The management of ductal carcinoma *in situ* detected by screening in Guildford has been primarily conservative with meticulous follow-up examinations by mammography Only one of the cases has progressed to microinvasion and this patient had received adjuvant radiotherapy The role of radiotherapy in management is controversial. Although acceptable local recurrence rates after excision and radiotherapy have been shown in non-controlled series[2,13], ductal carcinoma *in situ* may progress to invasive carcinoma following radiotherapy[2,13,14] and, as shown in our own series, might be resistant to radiotherapy[15,16]. Schnitt *et al.*[17] have reported a high rate of recurrence after radiotherapy for invasive cancer related to residual ductal carcinoma *in situ* adjacent to the excision biopsy site.

Information regarding steroid hormone receptor status of ductal carcinoma *in situ* is scarce[1] and there are no clinical data regarding the place of adjuvant tamoxifen. In this study, four women with segmental excision were commenced on tamoxifen.

The selection of patients for mastectomy was based primarily on the apparent extent of the disease; multiquadrant disease and some multicentric disease were treated by mastectomy. Anderson *et al.*[18] have ascribed a more aggressive behaviour to larger lesions and Lagios *et al.*[19] have shown a relationship between ductal carcinoma *in situ* $>2{\cdot}5$ cm and invasive cancer. Certainly the majority of quadrant sized ductal carcinoma *in situ* contain foci of invasive carcinoma[20] In this study many of the larger quadrant sized lesions have by surgical necessity been removed by mastectomy. However, those which have been suitable for conservative surgery have not shown a tendency to recur (*Figure 4*). Similarly, multifocal disease in the biopsy specimen is not related to recurrence It is of crucial importance to ensure that the central core of the breast is not involved by ductal carcinoma *in situ* before limited resection is performed and to this end all quadrant resections were accompanied by a central core and nipple core biopsy in this series.

There has been one only case of recurrent invasive cancer in the series, giving a 7-year actuarial progression rate of 8 per cent. Although the follow-up period is short, this tends to support the view that asymptomatic ductal carcinoma *in situ* is a less aggressive tumour than symptomatic ductal carcinoma *in situ*. Nevertheless, follow-up mammography examinations detected the local recurrence at an early stage of invasion before lymph gland metastases had occurred

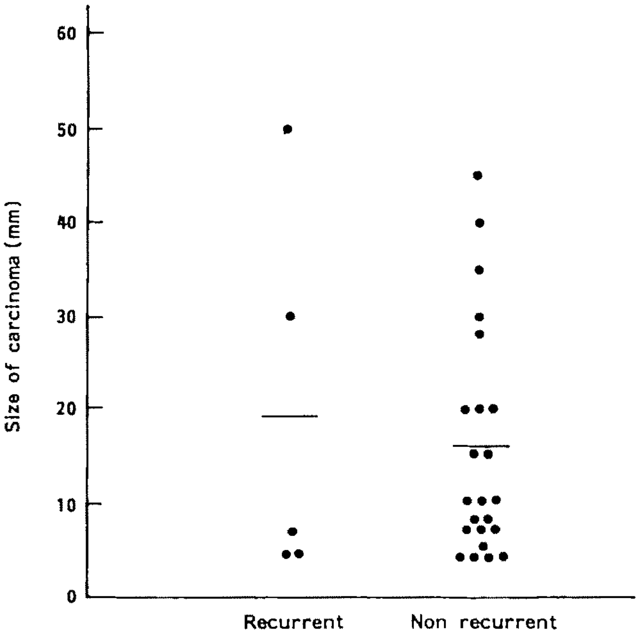

Figure 5 *Size of recurrent (mean = 19 mm) and non-recurrent (mean = 16 mm) ductal carcinomas Mann–Whitney* U *test. difference not significant*

Residual ductal carcinoma *in situ* was found in about two-thirds of breasts which were eventually removed by mastectomy, and this is comparable to previous studies[21,22]. There is therefore the implication that not all residual disease is biologically active[2], but breast cancer can have a protracted course, requiring long-term follow-up in all cases.

Using mammographic and pathological criteria to determine conservative treatment for apparently focal lesions, only one case of recurrent invasive cancer has occurred in 28 women with ductal carcinoma *in situ* treated conservatively and followed over 7 years. Follow-up is relatively short (mean 38 months); however, estimates of probability of local recurrence suggest that this will not alter appreciably with longer follow-up[2]. Annual mammography has detected all recurrences at an early stage (four as ductal carcinoma *in situ* and one as microinvasive cancer) and it is unlikely that more frequent mammography will improve detection rates of recurrence.

Our early findings indicate that screen detected ductal carcinoma *in situ* may behave in a more indolent manner than symptomatic ductal carcinoma *in situ*. Current preference for radical management may require re-evaluation, particularly in the light of a more conservative approach to the management of invasive breast cancer. Where good mammographic follow-up facilities exist, initial treatment of the majority of screen detected ductal carcinoma *in situ* has been safely accomplished by simple excision To date, any recurrence has been detected and dealt with at an early stage.

The aim of this study was to assess upper limb morbidity following treatment for operable breast cancer. Patients were randomized to either mastectomy and axillary clearance (40 women: 12 with axillary nodal metastasis and 28 without axillary metastasis) or mastectomy and axillary sampling (54 women). Adjuvant radiotherapy was delivered to those in whom the sample revealed axillary nodal metastasis (28 women) but not to those with no axillary nodal metastasis (26 women). A subjective assessment of the state of the arm was made using a standard questionnaire. Objective assessment included upper and forearm circumference, shoulder joint mobility and assessment of power in the pectoralis muscle. The mean age was 56·8 years (range 33–77 years) and the mean elapsed time from treatment was 5·72 years (range 4·0–7·5 years). Subjective limb oedema was greatest in those who had axillary lymph node metastasis but there was no objective difference. Subjective joint mobility was reduced in the women who received radiotherapy and this was confirmed by objective assessment ($P < 0.05$). The objective reduction in arm mobility was related to the treatment rather than the axillary lymph node status. There was no difference in power. In this study women receiving adjuvant radiotherapy had significantly reduced shoulder mobility. This may have implications for current conservation studies using adjuvant radiotherapy.

Keywords: Breast neoplasia, surgery, morbidity

The treatment of breast cancer with breast conservation has led to a resurgence in the use of radical radiotherapy both to the residual breast and as an alternative to surgical clearance of the axilla[1,2]. Surgery remains the principal initial treatment for early breast carcinoma but its extent and the role of radiotherapy, particularly in the management of the axilla, is still controversial. In the UK many surgeons still prefer to perform a mastectomy with either surgical clearance of the axilla or node sampling with radiotherapy only if there are metastatic deposits in the axillary nodes[3–5].

Late upper limb oedema is a recognized complication of either radiotherapy or surgery[6] and is most severe if the irradiated axilla has also been surgically cleared[7,8]. Previous studies assessing arm morbidity are difficult to interpret. For example, the influence of the initial selection is unclear and women with known local or distant recurrent disease, itself a cause of limb morbidity, were not always excluded[7,9,10]. Radiotherapy now utilizes megavoltage rather than orthovoltage X-rays which may require differing techniques with significantly different biological effect. Treatment with either radiotherapy or surgical clearance of the axilla does not appear to confer any survival advantage[11], so their relative morbidity assumes greater importance.

It therefore seemed appropriate to reappraise the morbidity of axillary treatment in the randomized group of women included in the Edinburgh sample-or-clearance trial[12,13]. In this trial women with operable breast carcinoma (T_{0-2}, $N_{0 \text{ or } 1}$, M_0) were prospectively randomized to be treated either by mastectomy and axillary clearance or mastectomy and node sampling, with adjuvant radiotherapy to the axilla being given only to women with metastatic deposits. Thus, four groups of women were available for assessment of morbidity: (1) women with axillary nodal metastasis treated by surgical axillary clearance (C+), (2) women without axillary nodal metastasis treated by surgical axillary clearance (C−), (3) women with axillary nodal metastasis treated by axillary node sample and radiotherapy (R), (4) women without axillary nodal metastasis treated by axillary sampling only (S).

Patients and methods

Only women in the Edinburgh sample-or-clearance trial known to be free of local or systemic disease were considered for this study. An unselected group of women, chosen alphabetically, were sent an invitation to attend a special clinic. Non-respondents received a further letter or telephone call Details of the initial randomization, surgery and radiotherapy were confirmed from trial and radiotherapy records only at the conclusion of the study. The women were specifically requested not to volunteer the nature of their treatment although in some it was obvious on clinical examination that they had received radiotherapy

At the clinic a single observer (RJ A.) recorded personal details and completed a standard questionnaire which recorded subjective impairment of daily activity. Objective assessment of arm swelling and shoulder mobility was assessed by measuring arm circumference 15 cm above and 10 cm below the olecranon[7,9] while the woman sat with her hands on her hips The median of three measurements was recorded Shoulder joint mobility was assessed by four methods: (1) adduction with internal rotation and (2) abduction with external rotation were assessed by measuring the woman's ability to reach behind her back and up or down the spine respectively using the C7 spinous process as the reference point; (3) the difference (between the treated and the non-treated arm) in height reached whilst standing face against a wall and stretching as high as possible; (4) measurement of an abduction movement without shoulder rotation whilst lying on a flat, hard surface. The power (centimetres per kilogram) of pectoralis major was assessed by the repeated lifting of a 3·5 kg weight as fast as possible over 45 s The treated and non-treated arm was assessed in each patient.

This paper was presented in part at the Association of Surgeons meeting in Harrogate in March 1988.

The treated and non-treated arms were compared within each group and in a second analysis the differences between the treated and non-treated arms were calculated and compared between the four groups.

Radiotherapy

In the original ('old') radiotherapy technique the supraclavicular fossa, shoulder and axilla were treated with semiopposed fields to a dose of 42·5 Gy in ten alternate-day fractions using megavoltage radiation with bolus to achieve dose homogeneity. Despite dose reduction to 40 Gy and the introduction of humeral shielding, late morbidity in the form of telangiectasia, subcutaneous fibrosis and osteonecrosis was still apparent

In 1982 the radiotherapy technique was revised to give a maximum dose of 45 Gy in 20 fractions over 4 weeks with megavoltage radiotherapy (the 'new' technique) The posterior field was reduced in size just to cover the axilla. Bolus was no longer used

Data handling and analysis

The data were stored and analysed on an Excel® (Microsoft Corporation, California, USA) spreadsheet using an Apple MacIntosh SE® (Apple Computer Incorporated, Cupertino, California, USA) microcomputer Statistical analysis was by Student's *t* test, the χ^2 test and the test for trend.

Results

The personal data of the women in this study are shown in *Table 1*; the study group represent 33·2 per cent of the women in the Edinburgh sample-or-clearance trial who were alive and disease free. Women who had an axillary clearance and were node negative differed from the other groups in that ten of the 12 carcinomas were in the right breast and the dominant arm was therefore more frequently implicated.

Subjective assessment (Table 2)

Although subjective arm swelling was similar in the women who were node positive (R and C+) and greater than in the women who were node negative (S and C−) this difference was not significant (test for trend: R *versus* C+, $P = 0·9$; S *versus* C−, $P = 0·55$; C+ *versus* C−, $P = 0·4$). The oedema was generally of a minor nature and no woman was inconvenienced by limb swelling. Significantly more women (16 of 28, 57 per cent) who received radiotherapy noted some shoulder stiffness (χ^2 test: R *versus* C+, $\chi^2 = 9·17$, $P = 0·003$; S *versus* C−, $\chi^2 = 1·07$, $P = 0·30$; C+ *versus* C−, $\chi^2 = 1·58$, $P = 0·21$). In four women (14 per cent) this significantly influenced their daily activities (test for trend: R *versus* C+, $P = 0·03$; S *versus* C−, $P = 0·74$; C+ *versus* C−, $P = 0·40$). Women in all groups commented that the treated limb easily tired but none found this a significant impediment.

Table 3 *Shoulder joint mobility (range of movement)*

	P values

Statistical analysis was by Student's *t* test. * The treated arm was always less mobile than the non-treated arm; † the range of movement in the first group was always less than the second group R, axillary nodal metastasis treated by axillary node sampling and radiotherapy; S, axillary sampling only without nodal metastasis; C+, axillary clearance with modal metastasis; C−, surgical axillary clearance without nodal metastasis

Objective assessment

There was no difference in any of the parameters assessed between the non-treated (control) arms of the four groups. Within each group the treated and non-treated arms were compared. There was no significant difference in limb circumference. In the node positive women, all shoulder joint movements were reduced in the women who received radiotherapy but in women who had an axillary clearance, only adduction and internal rotation was reduced (*Table 3*). In the node negative women there was no difference in shoulder mobility between the treated and non-treated arms (*Table 3*).

The difference between the treated and non-treated arms was calculated and women with similar axillary nodal status (R *versus* C+ or S *versus* C−) were compared. Women who had a surgical axillary clearance, regardless of nodal status, were also compared (C+ *versus* C−). There was no significant

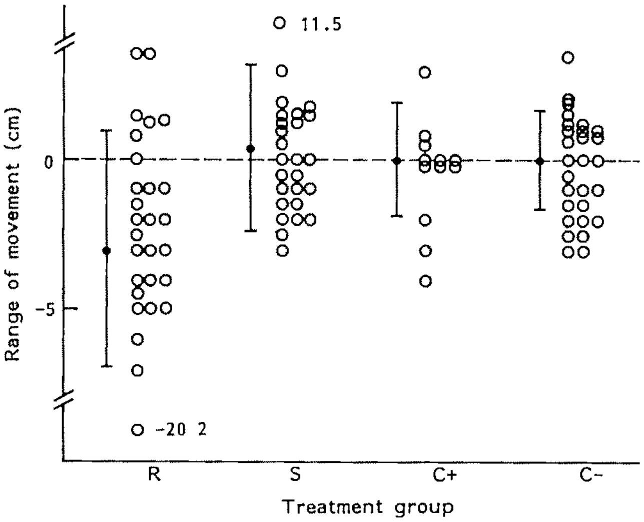

Figure 1 *The difference (mean and s d) in the range of movement (non-treated minus treated arm) with abduction and external rotation R, axillary nodal metastasis treated by axillary node sample and radiotherapy, S, axillary sampling only without nodal metastasis, C+, axillary clearance with nodal metastasis, C−, surgical axillary clearance without nodal metastasis. The range of movement in women receiving radiotherapy is significantly reduced Student's* t *test R* versus *C+*, t = −2·21, P = 0·033, *S* versus *C−*, t = −3·55, P = 0·340, *C+* versus *C−*, t = 0·39, P = 0·700

difference in limb circumference. In the node negative women there was no significant difference in the range of shoulder movement but, in the node positive women, mobility in women who received radiotherapy was significantly reduced in two of three movements when compared with women who had an axillary clearance (*Table 3*). As an example, the range of movement for abduction with external rotation is shown as a scatter graph in *Figure 1*.

There was no significant difference between any groups when measuring the height reached up the wall. The power of pectoralis major (treated *versus* non-treated arm) was reduced in women who received radiotherapy (Student's *t* test: $t = -2{\cdot}67$; $P = 0{\cdot}013$) but there was no difference between the four groups.

This analysis revealed no major difference between the women who had a clearance; the two groups were then combined (C+ and C−, 40 women) and compared with the women who had a node sample. This second analysis, with the women who had a clearance in a single group, confirmed there was no difference in arm circumference between the groups. The range of shoulder movement in women who had an axillary clearance was significantly greater than the women who had radiotherapy but there was no significant difference in the range of shoulder movement when compared with the women who had a node sample only.

Women who received radiotherapy were subdivided according to the radiotherapy technique used (16 and 12 women in the old and new techniques respectively). The trend suggested that those treated by the old technique had greater impairment of shoulder mobility but the numbers were small and these women had the longest follow-up time.

There was no consistent effect resulting from surgery to the dominant or non-dominant arm. There was no evidence to suggest that these differences were related to the presence of an implant.

Discussion

We have demonstrated that shoulder joint mobility in women who received radiotherapy to the chest wall and axilla was significantly impaired when compared with those in whom the axilla was only sampled or surgically cleared. This finding may have important implications for women now being offered breast conservation when the axilla is managed with radiotherapy rather than surgery[1,2]. The median follow-up time (5–6 years) in this study is short and, as the late complications of radiotherapy are irreversible and may be progressive, our results probably represent a conservative assessment of potential morbidity.

This study was deliberately designed to relate to the women's daily activities. Assessment of shoulder joint movement in a single direction is of limited value as almost all upper limb movements involve the whole shoulder girdle. In this study, four of 28 women (14 per cent) receiving radiotherapy had to make a major readjustment in life-style, such as giving up a recreational activity or using their other arm.

The principal difference between the women in this study was the nodal status: all the women receiving radiotherapy were axillary node positive and those who had a node sample only were all axillary node negative, whereas women who had axillary clearance could be either node positive or negative. These results reflect differences of treatment rather than the node status. Although there was no difference between women irradiated by the old and new techniques, evidence from a larger group of women suggests that rib necrosis and pulmonary fibrosis have been reduced with the introduction of the new technique.

Unlike previous reports[5,6,10], we did not find that arm oedema was prominent in this study and although subjectively greater in those with axillary lymph node metastasis this difference was not significant. Even on direct questioning, no woman volunteered swelling of any practical importance. There is no obvious explanation for the lack of arm swelling in this study but longer follow-up is required. Although others[5,6] have assessed limb oedema by volumetric methods, we have found that the wide normal variation in arm volume makes reliable comparisons difficult unless there is a preoperative assessment as a baseline; this was not available with these women.

Although there is no unanimity on the best way to treat the axilla, the morbidity secondary to radiotherapy is of concern and must be balanced against a possible increased incidence of axillary recurrence, although in this study there was no difference in the four groups[13]. As it is more difficult to perform a complete axillary nodal clearance when the breast is conserved, it will be important to assess women treated in this manner and Edinburgh women being entered into the current Scottish Conservation Trial are presently having a wide local excision and being randomized to either surgical axillary clearance or nodal sample with selective radiotherapy.

In conclusion, this study has demonstrated that shoulder joint mobility is significantly reduced following treatment of the axilla by nodal sample and radiotherapy rather than surgical axillary clearance. When we perform a mastectomy we now prefer to undertake an axillary node clearance.

Technique for operative cholangiography after endoscopic sphincterotomy

M. N. Vipond, C. Gatzen, J. N. Thompson and H. A. F. Dudley

Academic Surgical Unit, St. Mary's Hospital,
London W2 1NY, UK
Correspondence to: Mr M N. Vipond

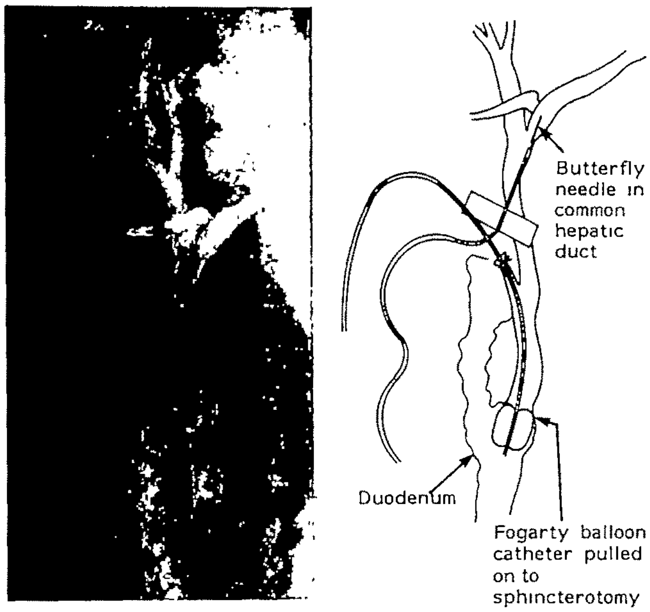
With the use of endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic sphincterotomy for common bile duct stones, cholangitis, papillary stenosis and in gallstone pancreatitis, an increasing number of patients will come to cholecystectomy with an incompetent sphincter of Oddi The majority of such operations are performed some time after sphincterotomy when the acute illness has resolved. For these patients the importance of accurate cholangiography is evident We present a simple, safe and effective method of operative cholangiography.

Technique

The cystic duct is dissected in the usual manner. The duct is opened and a 5 Fr biliary Fogarty catheter (Edwards Laboratories, Irvine, California, USA) is passed along the duct system to enter the duodenum via the sphincterotomy The balloon is inflated and the catheter drawn back on to the ampulla to occlude the sphincterotomy. Cholangiography is performed by direct puncture of the common bile duct using a 23 gauge 'butterfly' needle (Abbott Ireland Ltd , Sligo, Ireland) Films are obtained in the standard way and a final film is taken with the balloon deflated to confirm free flow of contrast into the duodenum. A cholangiogram obtained in this way is shown in *Figure 1*.

Discussion

ERCP and sphincterotomy have become established management for patients presenting with common bile duct stones. In patients with concomitant medical conditions endoscopic sphincterotomy may be definitive treatment, but a proportion of patients will come to cholecystectomy because of failure to clear the duct, or with persisting or recurrent symptoms[1]. In patients with severe acute pancreatitis of gallstone aetiology it has recently been proposed that urgent (within 72 h) ERCP should be carried out and, if stones are present, endoscopic sphincterotomy performed[2]. After resolution of the acute episode of pancreatitis cholecystectomy is recommended during the same hospital admission[3,4].



Butterfly needle in common hepatic duct
Duodenum
Fogarty balloon catheter pulled on to sphincterotomy

Figure 1 *An operative cholangiogram obtained by the method described and a schematic representation of the cholangiogram*

In patients who have had an endoscopic sphincterotomy for duct stones it is important that good-quality operative cholangiograms are obtained. However, the presence of a sphincterotomy makes it difficult to obtain filling of the whole biliary system. The use of the technique described here overcomes this problem.

Graft occlusion following aortofemoral bypass for peripheral ischaemia

A. R. Naylor*, A. K. Ah-See and J. Engeset

The Vascular Surgical Unit, Aberdeen Royal Infirmary, Forresterhill, Aberdeen, UK

Correspondence to:
Mr J. Engeset

Over a 10-year period, 241 patients with non-aneurysmal aortoiliac disease underwent aortofemoral bypass to 476 limbs. Four patients (1·7 per cent) occluded their grafts within 30 days of surgery, while 25 (10·4 per cent) suffered late graft occlusion. Postoperative occlusions were associated with significant morbidity and only one patient avoided major limb amputation or death. Overall, 46 episodes of graft thrombosis involving 51 graft limbs were encountered, the most common underlying cause being pre-existing or progressive multilevel distal occlusive disease. The overall cumulative graft patency rates were 95 and 87 per cent at 1 and 5 years respectively. Cumulative 5-year patency was significantly higher in patients presenting with claudication (91 per cent) than in patients presenting with rest pain (77 per cent) or ulceration and/or gangrene (71 per cent). Patients with evidence of multilevel distal occlusive disease at the time of aortic surgery had a significantly higher incidence of occlusion compared with those in whom there was no significant distal disease. In 35 episodes of occlusion (76 per cent), surgery was undertaken to restore limb blood flow, being successful in all but one case, with the most commonly performed procedure being graft limb thrombectomy. Seven of 28 patients (25 per cent) ultimately required major limb amputation and three patients died as a direct consequence of graft thrombosis.

Keywords: Aortofemoral bypass, graft occlusion

In the original 1952 report by Voorhees *et al.*[1] on the use of Vinyon 'N' cloth as a prosthetic replacement of the aorta, it was reported that 20 per cent of the experimental animals developed graft occlusion. In the intervening years, aortofemoral bypass has adopted an accepted place in the management of aortoiliac occlusive disease, but thrombosis remains the most commonly encountered graft-related complication during follow-up. This paper details our experience of graft occlusion in a consecutive series of 241 patients who underwent aortofemoral bypass over a 10-year period.

Patients and methods

A retrospective review was undertaken of 245 patients with non-aneurysmal aortoiliac occlusive disease who underwent aortofemoral bypass between January 1975 and December 1984 Four patients were excluded from analysis as no follow-up data were available. Patients have been regularly reviewed at the Vascular Clinic after surgery, although in a small number of patients, where long distances precluded clinic attendance, a questionnaire was completed by the family practitioner. The mean period of follow-up was 51 months (range 4–120 months) There were 171 men (71 per cent) with a mean age of 59·8 years (range 40–78 years) and 70 women (29 per cent) with a mean age of 59·9 years (range 45–76 years). Disabling claudication was the indication for surgery in 71 per cent of patients, while 29 per cent presented for limb salvage. The proximal aortic anastomosis was fashioned end-to-end in 160 patients (66 per cent) and end-to-side in 81 (34 per cent). An infrainguinal distal anastomosis was performed in 99 per cent of limbs; ten patients (4 per cent) underwent synchronous femorodistal bypass.

At the time of aortofemoral bypass, 207 limbs had no evidence of significant outflow or distal vessel disease, while 85 limbs were noted to have an isolated superficial femoral artery (SFA) occlusion in association with three-vessel run-off below the knee. Combined SFA occlusion, profunda femoris stenosis and/or occlusion and only one- or two-vessel run-off below the knee were present in 38 limbs

Statistical analysis was by Fisher's exact test and the log rank test with χ^2 analysis.

Results

Twenty-eight patients (11·6 per cent) had a total of 46 episodes of graft occlusion involving 51 graft limbs during follow-up. Twenty-four were men (mean age 56·9 years, range 42–74 years) and four were women (mean age 55 years, range 49–67 years). Seventeen patients had undergone a proximal end-to-end anastomosis and 11 an end-to-side. Four patients (1·7 per cent) suffered a graft occlusion within 30 days of surgery (one patient twice), while a further 25, including one patient whose graft occluded postoperatively, developed late graft occlusion. Two of the limbs with postoperative graft occlusion were noted to have poor distal run-off vessels, while no obvious underlying cause was identified in one patient. The remaining graft occluded in association with graft sepsis. Of the four patients, one died after a successful thrombectomy and femorodistal bypass and two required major limb amputation.

An acutely ischaemic leg was the presenting feature in 70 per cent of the 41 episodes of late occlusion, 30 per cent presenting with worsening claudication (13 per cent acute, 17 per cent a worsening of pre-existing claudication). The left graft limb was occluded in 65 per cent of episodes, the right in 24 per cent ($P = 0·007$), bilateral occlusions being present in five episodes. The times to graft occlusion with respect to the 46 episodes are detailed in *Table 1*, 30 per cent having occurred within 1 year of surgery and 87 per cent within 3 years.

Inflow pathology accounted for three (6 per cent) of the occlusions· two as a consequence of proximal aortic stenoses and one as a result of kinking of the graft. Systemic or other causes may have predisposed the graft to occlude in 12 episodes In six, a hypercoagulable state was proposed as the underlying cause (platelet dysfunction in two, polycythaemia in two, tumour induced thrombogenicity in two) Three patients

suffered graft occlusion in association with graft sepsis, while the cause was unknown in one patient. Two patients presented with a myocardial infarction and subsequently their grafts occluded as a consequence of prolonged hypotension, the grafts being noted to be patent on admission. The largest single group included those with outflow and distal vessel disease (31 episodes, 67 per cent). In two episodes, a stenosis at the femoral anastomosis was responsible for the occlusion, while in 29, there was evidence of pre-existing (58 per cent) or progressive (42 per cent) distal occlusive vessel disease. Three patients occluded their grafts while on therapeutic doses of anticoagulants, having been started on warfarin after a previous episode of graft thrombosis. There was no significant difference in 5-year graft patency rates: in men (84 per cent) and women (91 per cent, $P < 0{\cdot}2$), smokers (80 per cent) and non-smokers (91 per cent, $P < 0{\cdot}1$), and those with a proximal end-to-end anastomosis (87 per cent) as opposed to an end-to-side anastomosis (84 per cent, $P < 0{\cdot}5$). Patients presenting with claudication (*Figure 1*) had a significantly better cumulative 5-year patency rate (91 per cent) than those initially referred with rest pain (77 per cent, $P < 0{\cdot}05$) or ulceration and/or gangrene (71 per cent, $P < 0{\cdot}001$). There was no statistically significant difference in cumulative patency between the latter two groups of patients.

Claudicants who smoked postoperatively had a significantly lower 5-year patency rate (87 per cent) than non-smokers (96 per cent, $P < 0{\cdot}05$). Patients who smoked after limb salvage surgery had a lower 5-year patency (65 per cent) than non-smokers (82 per cent), although the difference did not reach statistical significance.

Outflow and distal vessels that showed no evidence of occlusive disease at the time of aortic surgery (*Figure 2*) had significantly better 5-year patency rates (97·7 per cent) than limbs with an isolated SFA occlusion (91·2 per cent, $P < 0{\cdot}05$). The worst patency rates occurred in patients with a SFA occlusion in association with profunda femoris occlusion or stenosis and only one- or two-vessel run-off below the knee (5-year patency 67 per cent).

In 11 of the 46 episodes of occlusion, no surgical intervention was undertaken. In four patients this was because they had presented late and were living within their claudication distances. Three grafts reoccluded in the postoperative period after thrombectomy and were not subjected to further clearance because of poor distal vessels, while a further two patients were not operated on as their diseased vessels would not support the graft. The two patients whose grafts occluded after myocardial infarction were not submitted to surgery; one of the patients subsequently died.

In 35 episodes of occlusion (*Table 2*) surgical intervention was undertaken. In four, graft thrombectomy proved impossible and limb blood flow was restored by extra-anatomical bypass. Three patients (two with coexistent sepsis) underwent either total or partial graft excision as the primary procedure, limb blood flow being restored in two and poor distal vessels precluding reconstruction in the third.

In 28 episodes (80 per cent), graft thrombectomy was successfully undertaken and in 14 cases, no additional procedure was performed. Despite undergoing a successful thrombectomy, the grafts of a significant proportion of patients subsequently reoccluded with one patient suffering six episodes of thrombosis. Cumulative patency after the first successful graft thrombectomy was 68 per cent at 1 month, 48 per cent at 1 year and 30 per cent at 5 years If, however, the data are expressed as cumulative 'extended' patency in the manner of Brewster *et al.*[2] (this allows for repeatedly successful graft thrombectomies to be included with the patent graft limb group after the first

thrombectomy), 90 per cent of grafts were patent at 1 month, 84 per cent at 6 months and 71 per cent at 5 years

Seven of 28 patients (25 per cent) ultimately required major limb amputation (five above-knee, two below-knee) including the two patients whose amputations followed postoperative occlusions Six had evidence of poor distal run-off, in three the main graft occluded in the postoperative period after an earlier graft thrombectomy and in two it was in association with graft sepsis Only one patient required amputation in the presence of a patent aortic graft having undergone a successful thrombectomy and femorodistal bypass, although this patient subsequently died from acute renal failure. Three patients died as a direct consequence of graft occlusion and its sequelae. Acute renal failure was the cause of death in two patients, one in the postoperative period after successful thrombectomy and femorodistal bypass, while the second with graft sepsis died after graft excision and revascularization. The remaining patient suffered a myocardial infarction after an unsuccessful graft clearance and axillofemoral bypass. There have been no deaths after thrombectomy alone

Discussion

Thrombosis was the most commonly encountered graft-related complication in patients undergoing aortofemoral bypass in our unit[3]. Our incidence of 1·7 per cent in the postoperative period compares favourably with the results of other studies[4–9], although it is significant that only one of the four patients avoided either death or major limb amputation. Acute limb ischaemia was the presenting feature in 70 per cent of late episodes and this is in accordance with the experience of others[2,7,8], emphasizing the importance of early referral and management We found no significant differences in cumulative patency rates: between men and women, in the different modes of proximal anastomosis, in the presence or absence of diabetes, in the presence or absence of hypertension; although others have reported a higher incidence of graft occlusion in men[2], women[6] and end-to-side proximal anastomoses[11]. As with Najafi *et al.*[7], we found a higher incidence of thromboses involving the left graft limb. While others have reported a significant association between smoking and graft occlusion[4,6,10], the difference did not reach statistical significance in this study Claudicants who smoked postoperatively were significantly more likely to occlude their grafts than non-smokers, and while similar trends were evident in the limb salvage group the relatively small numbers involved did not reach statistical significance. Patients presenting with claudication had a significantly lower incidence of graft occlusion than patients undergoing surgery for limb salvage, reflecting the fact that claudicants have better distal vessels at the time of aortic surgery than limb salvage patients Satiani *et al.*[10] found a higher incidence of thrombosis in patients with rest pain as opposed to those with ulceration or gangrene, although no significant difference was evident in this study

It is now generally accepted that the fate of the graft is closely related to the state of the vessels distal to the femoral anastomosis[2,8,9] and our experience is in accordance with this. While Nevelsteen *et al.*[8] found no significant difference in subsequent graft occlusion in patients with evidence of SFA occlusion at the time of aortofemoral bypass, this was not borne out in this study Patients with an isolated SFA occlusion had a significantly worse cumulative limb patency rate than patients having limbs with no evidence of distal occlusive disease. These findings are similar, but not as marked as those reported by Harris *et al.*[12], where the cumulative 5-year patency was 98 per cent in patients with no significant distal vessel disease, falling to 65 per cent where the SFA was occluded

Malone *et al.*[9] noted that all patients with combined profunda and trifurcation disease thrombosed their grafts within 5 years and that, in the absence of distal disease, only 5 per cent of grafts would occlude during follow-up. Those patients in this study with combined SFA and profunda femoral artery disease in association with diseased run-off vessels below the knee fared worst of all with a cumulative 5-year patency rate of 67 per cent.

Current concepts in the management of graft occlusion include thrombectomy (with or without synchronous distal reconstruction), graft limb excision and prosthetic interposition, extra-anatomical bypass and thrombolytic therapy[2] We have had no experience of the latter. The recent study of 157 episodes of graft limb occlusion by Brewster *et al.*[2] has led them to advocate thrombectomy as a consequence of 'increased confidence in its feasibility and reliability'. In their series, thrombectomy was successful in all postoperative occlusions and in 95 per cent of late thromboses. Although the cumulative patency of the cleared grafts was only 47 per cent at 5 years, they found that with repeated thrombectomies, the cumulative 'extended' patency was 74 per cent at 5 years These findings are similar to our own experience

Our current policy is to undertake graft limb thrombectomy whenever possible Patients who present late and who are able to live within their claudication distance, having developed a satisfactory collateral circulation, are not generally referred for surgery. Those patients whose grafts reocclude in the postoperative period after thrombectomy are not subjected to further surgery if the distal vessels are poor. Those patients whose grafts remain occluded after attempted thrombectomy are considered for extra-anatomical bypass Repeat thrombectomies are performed as they are required, at which time distal reconstruction may be considered particularly for those with critical ischaemia. In our experience however, these patients usually have such poor distal vessels that reconstruction is often not possible and was only undertaken in seven of our patients. Where synchronous femorodistal bypass was performed at the time of thrombectomy, one patient died postoperatively and two patients suffered further episodes of aortic graft occlusion during follow-up.

Death as a consequence of graft limb occlusion is usually associated with multiple synchronous procedures[2], particularly if they are in association with complicated forms of occlusion such as sepsis[3]. We have encountered no deaths so far after graft thrombectomy alone

It is inevitable, bearing in mind that 60–80 per cent of occlusions present with critical limb ischaemia[2,7,8], that major limb amputation will be necessary in some patients. Seven patients in this study (25 per cent) ultimately required amputation and this corresponds with the 14–32 per cent experience of others[2,7,10,13]. It is essential, therefore, that these patients are referred as early as possible for surgical intervention although, in our experience, the delay to referral has occasionally been as long as 1 year.

Innominate vein compression syndrome

A. Wurtz, P. Quandalle, L. Lemaitre* and Y. Robert*

*Clinique Chirurgicale Ouest and *Service de Radiologie Ouest, Hôpital Claude Huriez, Chu, 59037 Lille Cedex, France*

Correspondence to: Dr A. Wurtz

Superior vena caval syndrome is often caused by a malignant process. We report an unusual case due to intermittent compression of the left innominate vein (LIV) by the origins of the aortic arch vessels.

Case report

In November 1986, a 65-year-old hypertensive and atheromatous woman complained of left anterior chest wall oedema, predominately in the breast and extending to the left side of the neck. 'Unilateral superior vena caval syndrome'[1] was diagnosed and heparin treatment was started. The oedema decreased but venous dilatation over the left upper thorax persisted. Chest radiography was normal. Venography demonstrated a filling defect in the LIV, suggestive of thrombosis or intraluminal tumour, a prethrombotic dilatation, and opacification of the left vertebral vein and vertebral plexus (*Figure 1*). A computed tomographic (CT) scan, at the supra-aortic level, showed no tumour in the mediastinum and the LIV was clear and rather dilated. Because of these discordant findings, digital subtraction angiography was performed in the left posterior oblique position. It showed extrinsic compression of the LIV by the origins of the aortic arch vessels (*Figure 2*).

To explain this bizarre obstruction, dynamic phlebography, with injection of contrast medium into the axillary vein, was performed, which showed normal blood flow in the LIV at end inspiration and extrinsic compression during expiration, increasing during forced expiration. The main point of obstruction was the left subclavian artery (*Figure 3*).

An additional CT scan included anteroposterior measurements of the sternal–spinal distances. At the thoracic inlet, this diameter was 4 cm, corresponding to the lower limit in an average adult[2]. At the aortic arch level, the anteroposterior diameter was 9 cm at end inspiration and 6 cm at end expiration. A bolus injection of contrast medium at the supra-aortic level showed (1) moderate compression of the LIV arising from the brachiocephalic trunk and left carotid artery, independently of the left subclavian artery, and (2) elevation of the aortic arch during expiration with the brachiocephalic trunk and left carotid artery increasing their compression of the LIV, but the left subclavian artery causing a complete interruption of the venous blood flow (*Figure 4*).

We conclude that this unilateral superior vena caval syndrome was due to intermittent compression of the LIV by the supra-aortic trunks, mainly the left subclavian artery, during expiration.

The left superficial venous dilatation remains unchanged 22 months after the original presentation.

Discussion

Aortic aneurysm is a common cause of benign superior vena caval syndrome, but extrinsic compression by a non-aneurysmal artery has not been reported[3,4], nor has unilateral superior vena caval syndrome[1]. However, some authors have previously described LIV compression by the aortic arch, leading to myelopathy, which was treated by partial resection

of the anterior chest wall[5]. Such treatment seemed excessive for our patient.

Obstruction of the LIV by the left subclavian artery has never been described and the late development of symptoms may be due to arterial atheroma coupled with a narrow superior mediastinum. The remission of acute symptoms with heparin treatment was suggestive of initial venous thrombosis.

Compression of the left common iliac vein by the right common iliac artery due to an anatomical anomaly ('iliac compression syndrome' or 'Cockett's syndrome'[6,7]) is well known and acquired cases have been related to 'coiling' of an atheromatous iliac artery[8].

The case described here is a thoracic equivalent of Cockett's syndrome and so can be called 'innominate vein compression syndrome'.

A reduction in the 'elasticity' of the venous system has been proposed as a precursor of venous insufficiency, but the concept remains controversial. This study was designed to develop a method of assessing venous elasticity, and to use this method to investigate the aetiology of varicose veins. Simultaneous measurements of calf volume (determined using strain gauge plethysmography) and venous pressure (obtained via a dorsal foot vein) were made during venous occlusion plethysmography. The elastic modulus, K, defined as stress/strain when the veins are full, was calculated from the pressure/volume relationship. The elastic modulus was determined in 19 normal legs, 33 legs with superficial venous insufficiency, 16 legs with deep venous insufficiency, and 18 legs of a high risk group of volunteers or patients without varicose veins but with a strong history of factors associated with their development. The results showed a clear difference in elasticity between normal limbs and limbs with varicose veins, and also between normal limbs and high risk limbs. These results support the hypothesis that reduced elasticity has a role in the development of varicose veins and precedes the onset of valvular incompetence.

Keywords: Varicose veins, elasticity, plethysmography, venous pressure

Varicose veins are usually associated with dilatation and malfunctioning venous valves, which allow venous reflux to occur. Progression of the disease results in more pronounced dilatation and increased severity of reflux. The interaction between these two phenomena has not been determined and it is not clear whether the valvular incompetence occurs first and produces the dilatation, or vice versa.

A number of workers who have performed *in vitro* investigations into the pathology of varicose veins have suggested that the valvular incompetence associated with varicose veins arises following venous dilatation[1,2]. In contrast, *in vivo* investigation into the significance of the external iliac and femoral valves[3] has shown some association between a positive family history and the absence of these valves: also between impaired function of these valves and varicose veins.

Examination of the various theories about the development of varicose veins suggests that the weak wall theory is the most likely[4]. The manifestation of venous dilatation and associated mechanical weakening of the vein wall before the onset of valvular insufficiency has not been demonstrated.

Methods for assessing valvular function include the accepted standard of ambulatory venous pressure (AVP) measurements[5] and duplex Doppler scanning[6,7]. A similarly established method for assessing the function of the vein walls does not exist and until one becomes available the mechanisms underlying the development of primary varicose veins remain a matter for speculation[8].

The purpose of this study was to develop a method of assessing the vein wall function in order to investigate the role of venous elasticity in the development of varicose veins.

Patients and methods

Patient selection

In this study 19 volunteers (27 limbs) and 45 patients (59 limbs) referred from the vein clinic were investigated. The 86 limbs studied were classified into the four groups: normal, high risk, superficial vein incompetence, and deep vein incompetence, as shown in *Table 1*.

Limbs without varicose veins were classified as either normal or high risk, using the following criteria: family history of varicose veins, occupation involving standing, history of symptoms and signs associated with varicose veins, presence of reflux detected with Doppler ultrasound, and abnormal AVP recordings of >40 mmHg and RT_{90} (time required to achieve 90 per cent filling) <18 s.

If two or more of these criteria were present the limb was classified as being at high risk of developing varicose veins (18 limbs). Otherwise it was classified as normal (19 limbs).

The limbs with varicose veins or established venous disease were classified into two haemodynamic groups using AVP measurements and duplex scanning: superficial venous incompetence (33 limbs) and deep venous incompetence (16 limbs).

The measurement of elasticity

The experimental method used is shown in *Figure 1*. It combines standard strain gauge plethysmography[9,10] with venous pressure measurements. The patient was placed supine with one leg elevated 27 cm at the heel to allow the veins to empty. The knee was flexed and externally rotated and the thigh was supported to ensure that the leg was relaxed. Strain gauge plethysmography was performed using an electrically calibrated mercury in Silastic® (Dow Corning, Reading, UK) strain gauge (Perivein® JSI 0539/1, Janssen Pharmaceutical Ltd., Wantage, UK) placed around the calf at its maximum circumference, allowing percentage volume change to be determined. Measurements of venous pressure were obtained by inserting a 21-gauge butterfly needle into a vein on the dorsum of the foot. The strain gauge plethysmograph and pressure monitor were connected to a two-channel chart recorder, allowing simultaneous measurements of pressure and volume to be made.

The pressure:volume relationship of the lower limb venous system was obtained by inflating a 17-cm wide cuff placed around the thigh to 80 mmHg to occlude the venous outflow. Typical recordings of the

subsequent changes in pressure and volume are shown in *Figure 2*. Simultaneous readings of pressure and volume were taken from the recordings every 15 s and plotted on a graph.

The change in pressure (ΔP) and the corresponding change in volume (ΔV) were measured in the linear, high pressure part of the pressure:volume curve. This linear region of the curve and the initial slope were extrapolated, as shown in *Figure 3*, to obtain the theoretical value of the initial volume V_0 pertaining to the changes in volume at high pressures. The elastic modulus, K, was calculated by substituting P, V, and V_0 in equation (1). This was converted to the International System of Units (millimeters of mercury to newtons per metre squared) using a standard conversion factor of 132·9.

$$K = \frac{\Delta P}{\Delta V / V_0} \qquad (1)$$

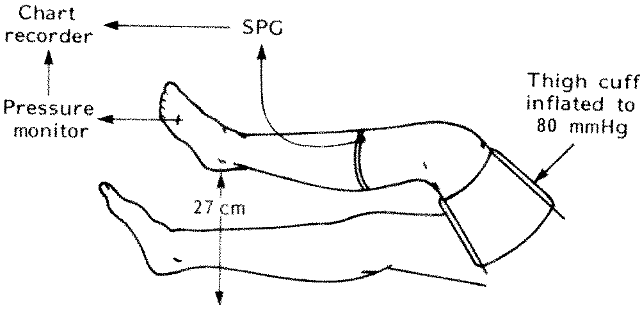

Figure 1 *The simultaneous measurement of pressure and volume with proximal occlusion. SPG, strain gauge plethysmograph*

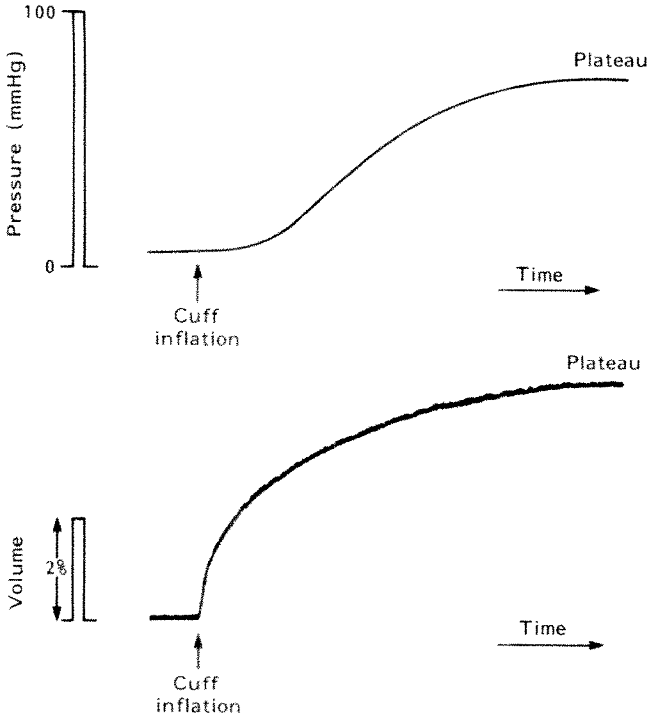

Figure 2 *Simultaneous recordings of pressure and volume obtained during venous occlusion*

This method of calculating the elastic modulus is inherently variable owing to the difficulty in determining the extent of the linear region of the curve and selecting the gradient. In order to standardize this a maximum and minimum gradient were obtained from each group and the mean value was used to calculate the elastic modulus. The maximum and minimum values were also used to determine the experimental variation (EV), which was then expressed as a coefficient of EV:

$$EV = \left[\frac{\sum (\mathrm{Max} + \mathrm{Min})^2}{2n}\right]^{\frac{1}{2}} \qquad (2)$$

$$\text{Coefficient of } EV = \frac{EV}{\bar{K}} \times 100 \qquad (3)$$

where n is the number of limbs, and $\bar{K}$ is the mean elastic modulus. This coefficient of experimental variation was calculated for each patient group.

Results

The number of limbs in each of the four groups and the results are summarized in *Table 2*. The elastic modulus, K, in individual limbs is shown in *Figure 4*, using a logarithmic scale because of the comparatively high values in the normal limbs. The elastic modulus is higher in the normal group than in either the high risk group or the two patient groups. There is no discernible difference in elasticity between the high risk group and the two patient groups. In the normal group there is a wide range in the measured elasticity but this group remains distinct from the other three groups.

Discussion

The method used to calculate the elastic modulus K is based on the relationship between the pressure/volume curve and the mechanisms of venous filling. At low pressures veins are empty and become collapsed. As the veins fill, two mechanisms control the venous filling[11]. Firstly, there is flexion of the walls as the

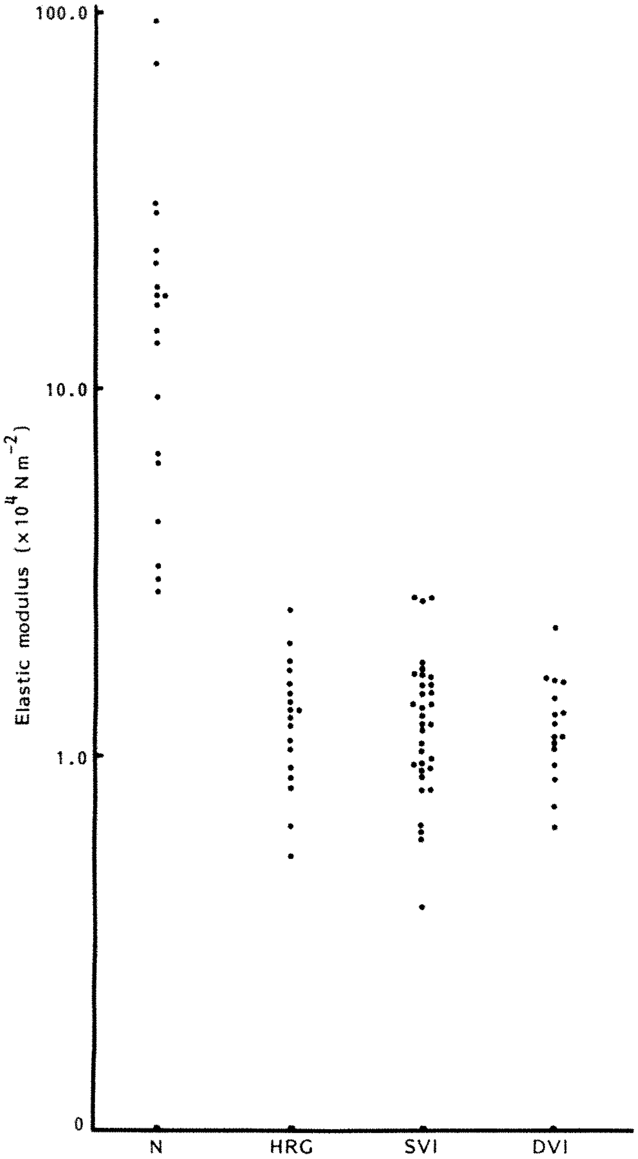

Figure 4 *The elastic modulus,* K, *for the four patient groups: N, normal; HR, high risk; SVI, superficial vein incompetence; DVI, deep vein incompetence*

collapsed veins fill to an elliptical and then circular cross-section; secondly, there is stretching of the vein wall which increases the circumference of the veins. The changes in vein configuration associated with venous filling and the pressure/volume relationship are shown in *Figure 5*. At low pressure flexion is the predominant mechanism whilst at high pressures stretching is predominant. In the initial phase filling occurs from a combination of both mechanisms.

Of these two mechanisms of venous filling it is stretching, rather than flexion, that is related to the dilatation and mechanical weakening of vein walls associated with venous disease. It is this aspect of the pressure/volume relationship that has been analysed, since the stretching of a vein is governed by its elasticity.

Elasticity is usually quantified in terms of an elastic modulus: K = stress/strain, where stress is the force per unit area, i.e. ΔP, and strain is the increase in volume per unit volume, i.e. $\Delta V/V_0$. Thus,

$$K = \frac{\Delta P}{\Delta V/V_0} \qquad (1)$$

The change in pressure and the change in volume were measured in the linear region of the curve where stretching predominates (*Figure 3*). Since K is a measure of vein stretching rather than flexion the theoretical initial volume, V_0, is the percentage volume measured when the veins have reached circular cross-section and are unstretched.

The measurements of the elastic modulus, K, indicate that the elasticity in normal limbs is higher than that in limbs with or at high risk of developing venous disease (*Figure 4*). The difference between normal limbs and limbs with established venous disease complies with theoretical expectations which predict that higher venous pressures weaken the vein walls with consequent deterioration of their mechanical properties. This difference also indicates that the measurement of the elastic modulus provides a means of assessing vein wall function in the lower limb.

The results indicate that this method cannot differentiate between the function of vein walls in the deep and superficial systems. This is because if any vein within the venous system has weaker functioning walls, filling of this vein swamps the measured changes in volume at the higher pressures, which results in a low measurement of elastic modulus. Thus the elasticity of the lower limb venous system is lowered by the behaviour of one vein, regardless of whether it is located in the deep or superficial system.

As the elastic modulus is obtained by measuring the gradient of the pressure/volume curve, the accuracy of each measurement depends partly on discrimination between the linear and the curved regions of the graph. In most cases this was clear and in consequence there was little difference between the maximum and minimum gradients, and the possible variation in K was low. In six cases, however, the linear region of the curve was not clear and there was a large difference between the maximum and minimum gradients. These cases were largely responsible for the high coefficient of maximum experimental variation.

The identification of patients in the early stages of venous disease is crucial to a study of the development of varicose veins. As most patients presenting in the vein clinic had more advanced disease, this posed a problem. Following recent work[12], the concept of finding venous disease in the normal contralateral limb of a patient with venous ulceration has been considered. Extending this idea it seems reasonable to expect that a number of the normal population might also have some degree of venous disease. This led us to the conclusion that there were two potential sources of patients in the early stages of the development of varicose veins. Firstly, there were the normal contralateral limbs of patients with unilateral disease and, secondly, there were volunteers from the so-called normal population.

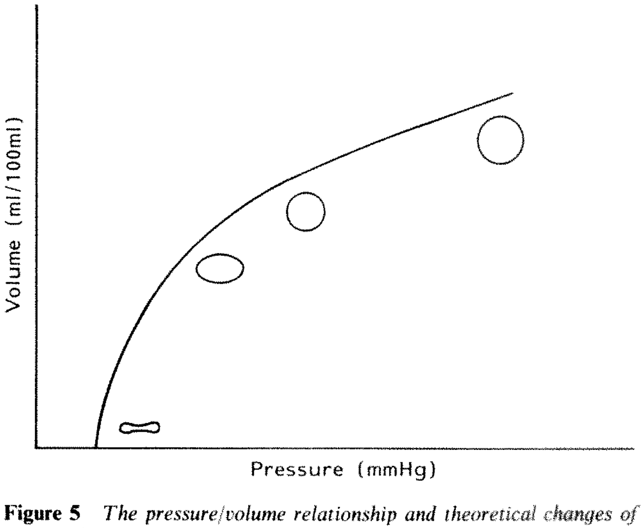

Figure 5 *The pressure/volume relationship and theoretical changes of vein configuration*

The separation of non-varicosed limbs into two groups of either normal limbs or limbs in the early stages of the development of venous disease was achieved by a combination of risk factors and measurements. As there is no evidence that the limbs classified as being in the early stages of disease will in fact develop varicose veins, these limbs have been defined as a high risk group.

The clear distinction between low risk normal limbs and limbs with established venous disease, and between low and high risk normal limbs suggests that the role of elasticity in the development of varicose veins precedes the valvular incompetence. This cannot be proved until follow-up data are obtained to establish the subsequent development of varicose veins in clinically normal high risk limbs with a low elastic modulus. The results of the present study, however, provide preliminary evidence in support of the weak wall theory of the development of varicose veins.

Although incompetent thigh perforating veins are considered to be a common cause of recurrence of varicose veins after high saphenous ligation, the number and distribution of such incompetent veins have not been reported. The aim of the study was to determine the number and anatomical distribution of incompetent thigh perforating veins. Sixty-five limbs in 48 patients with varicose veins who were found to have incompetent thigh perforating veins on ascending deep to superficial venography were studied. In 80 per cent of patients one incompetent thigh perforating vein was found and in 20 per cent more than one was found. Concomitant incompetent calf perforating veins were found in 92 per cent of the limbs studied. The incompetent thigh perforating veins were found to occur anywhere in the thigh, from the upper edge of the patella to a few centimetres below the saphenofemoral junction. The majority (71 per cent) were found in the middle third of the thigh. All incompetent thigh perforating veins were communicating with the long saphenous vein, including those in five patients with incomplete stripping. The surgeon should be aware of incompetent thigh perforating veins which may be multiple and occur at any site on the medial aspect of the thigh.

Keywords: Varicose veins, incompetent perforating veins, anatomical distribution

There is an increased awareness that incompetent thigh perforating veins are a common cause of postoperative recurrence of varicose veins[1,2] and that in some patients they may even be a cause of varicose ulceration[3,4]. Despite this the sites and number of incompetent thigh perforating veins have not been reported, in marked contrast to the relatively large number of studies on incompetent calf perforating veins[5–8]. A search of the literature has revealed publications based on anatomical and surgical dissections[9–12] describing the anatomy of the normal perforating veins in the thigh rather than the distribution of the incompetent veins. Because of the surgical implications the purpose of our study was to determine the sites, distribution and number of incompetent thigh perforating veins in patients shown to have such incompetent veins by venography.

Patients and materials

Patients

Forty-eight patients who presented with varicose veins in 65 legs and who were found to have incompetent thigh perforating veins on ascending deep to superficial venography have been included in this study. Venography was part of the routine investigation of patients with varicose veins in whom, because of the clinical examination, tourniquet tests and Doppler ultrasound examination, incompetent thigh perforating veins were suspected. Patients whose venograms did not confirm the presence of such perforating veins were excluded from the study.

Forty-two of the 48 patients had had a previous operation for their varicose veins; 37 (50 legs) had ligation of the saphenofemoral junction without stripping and five (six legs) had ligation with stripping of the long saphenous vein.

None of the patients had a history of deep venous thrombosis, and reflux was not detected in the popliteal vein by Doppler ultrasound[13,14] or venography although five had lower leg ulceration. *Table 1* summarizes the clinical information of the patients.

Technique of venography

A vein on the dorsum of the foot was cannulated using a butterfly needle (21G) through which meglumine sodium ioxalate 320 (Hexabrix 320®, May and Baker, Dagenham, UK)) was injected. A narrow (2·5 cm) pneumatic cuff was applied to the ankle so that the contrast medium was directed into the deep veins. The radiographic table was tilted 60° to the horizontal (head up) and the progress of the contrast medium was followed using an image intensifier.

The presence of incompetent calf perforating veins, as indicated by the flow of contrast medium from the deep to the superficial veins, was noted and films were taken. When contrast medium entered the lower popliteal vein, the competence of its valves was tested by manually compressing the calf muscles and following the direction of flow of the column of blood and contrast medium. Retrograde flow on release of the compression indicated popliteal reflux; flow only proximally with absence of reflux confirmed a competent popliteal system (patients with popliteal reflux were excluded from the study). With further injection of contrast medium and the use of Valsalva's manoeuvre the superficial femoral vein and incompetent thigh perforating veins were visualized: contrast medium was seen to flow from the superficial femoral vein through the perforating veins to the superficial system, either the long saphenous vein or a tributary. A special ruler with radio-opaque markings was positioned on the medial aspect of the limb with zero at the level of the knee joint (under direct fluoroscopy) so that the level of a perforating vein in terms of its distance from the knee could be

attained. Finally, when contrast medium reached the common femoral vein the calf muscles were compressed, again in order to detect the presence or absence of reflux at the saphenofemoral junction immediately after release of the compression.

Results

Of the 65 limbs with incompetent thigh perforating veins studied, 56 had undergone a previous operation for varicosities (*Figure 1*). Fifty had a high saphenous ligation without stripping and six with stripping of the long saphenous vein. The incidence of reflux (recurrent or persisting) in the region of the saphenofemoral junction demonstrated by Doppler ultrasound and venography is also shown in *Figure 1*. It was present in a total of 21 (32 per cent) limbs.

The number of incompetent thigh perforating veins was one in 52 (80 per cent), two in 12 (18·5 per cent) and three in one (1·5 per cent) of the 65 limbs. Concomitant incompetent calf perforating veins were present in 60 (92 per cent) of the 65 limbs studied. An example of two incompetent thigh perforating veins is shown in *Figure 2*.

The distribution of the incompetent thigh perforating veins measured in centimetres from the knee joint is shown in *Figure 3*. Because the length of the femur and thigh vary according to the height of the patient, the results have been normalized by expressing the site of each incompetent perforating vein as a percentage of the length of the femur. The knee joint was zero and greater trochanter was 100 per cent (*Figure 4*).

The distribution per quarter of the femur or per third of the thigh (whole thigh: 0–75 per cent) is shown in *Figure 5*. It can be seen that 19 per cent are in the lower third, 71 per cent are in the middle third and 10 per cent are in the upper third of the thigh.

Table 2 shows the time to recurrence of varicose veins in relation to the original operation: high saphenous ligation only or high saphenous ligation with stripping.

Discussion

Sherman[9] first studied thigh incompetent perforating veins. His interest was aroused by a high 'recurrence' rate of varicosities (46 per cent), many attributed to thigh incompetent perforating veins in patients he had treated by flush ligation of the saphenofemoral junction and its tributaries followed by the injection of a sclerosing solution into the varices. He drew attention to the numerous anatomical variations and stated that although perforating incompetent veins could be found anywhere between the knee and the groin there were four constant sites: (a) the mid-Hunter canal vein, (b) the subsartorial vein, (c) the lower subsartorial vein, and (d) a perforating vein from the long saphenous to the femoral vein 6–8 cm below the saphenofemoral junction.

Dodd[3] also studied 52 limbs with varices for the presence of thigh incompetent perforating veins by exposing the Hunterian canal at operation. In 12 limbs the varices had not been treated earlier, but in the remaining 40 the varices had 'persisted' despite a previous operation. The number of incompetent perforating veins found were one in ten patients, two in another ten patients and three in one patient. The lowest

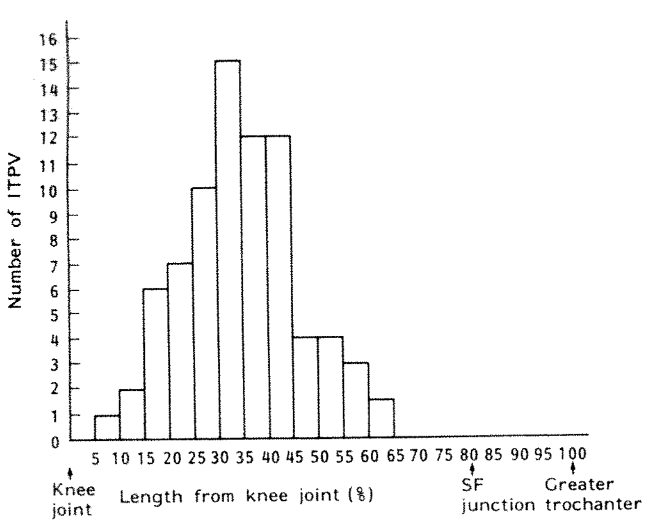

Figure 4 *The distribution of incompetent perforating veins in the thigh (ITPV) with their distance from the knee joint expressed as a percentage of the length of the femur. SF, saphenofemoral*

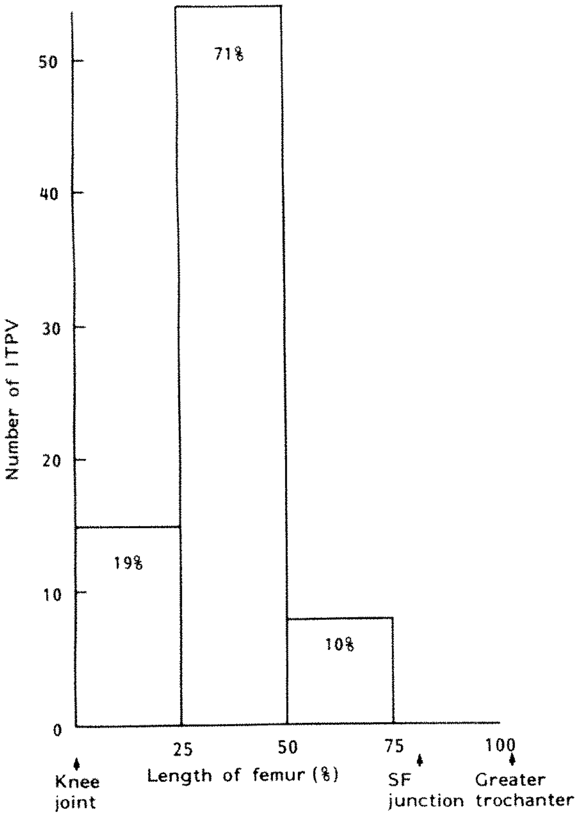

Figure 5 *The distribution of incompetent perforating veins in the thigh (ITPV) in each quarter of the femur or third of the thigh (thigh: 0–75 per cent). SF, saphenofemoral*

of the three perforating veins exposed in the canal was the one most commonly found to be incompetent. Dodd concluded that 'varicose communicating veins passing into the superficial femoral vein through Hunter's canal are often missed in diagnosing varicose veins, and are a cause of persistent varices after operation'[3].

From a large series of anatomical dissections van Limborgh *et al.*[11] and van Limborgh and Hage[12] classified the thigh performing veins into three groups: medial, lateral and posterior. They emphasized that the medial group is surgically the most important because of its connections to the long saphenous vein and the frequency of incompetence.

Because of the wide variation in the position of the thigh incompetent perforating veins and the need to avoid a long incision along the thigh as described by Dodd[3], Doran and Barkat[15] advocated deep to superficial venography to localize them. They claimed that the identification of the veins and their site saved many patients from unnecessary or unsuccessful operations.

The high incidence (39 per cent) of incompetent thigh perforating veins in patients with recurrent varicose veins (38 limbs) has been confirmed recently by varicography[1]. Sutton and Darke[4] have emphasized the need to strip the long saphenous vein in the thigh in order to disconnect such perforating veins from the superficial system. In our study all incompetent thigh perforating veins communicated with the long saphenous vein; this included the five patients who had incomplete stripping presumably because a large branch rather than the main trunk was stripped.

The aim of our study was to determine the number and anatomical distribution of the incompetent perforating veins along the thigh. Previous similar studies[3,9–11] have used clinical identification and surgical dissection rather than deep to superficial venography to identify these veins. Thigh incompetent perforating veins can be demonstrated using Valsalva's manoeuvre during ascending venography with an accuracy of 80 per cent, as judged by surgical exploration[16]. It should be pointed out that the effectiveness of the Valsalva manoeuvre becomes distally progressively less and it is possible that in some patients the number of incompetent perforating veins has been underestimated.

Our results indicate that incompetent thigh perforating veins can exist anywhere along the course of the long saphenous vein in the thigh, from the upper edge of the patella to a few centimetres below the saphenofemoral junction, although 70 per cent can be found along its middle third, an area that corresponds anatomically with the adductor canal. In 20 per cent of our patients there was more than one incompetent thigh perforating vein and this finding has important surgical implications.

The coexistence of 92 per cent of incompetent calf perforating veins suggests that in these patients varicose veins were the result of a more generalized disease rather than of just a few localized incompetent sites.

A number of questions remained unanswered. Were these incompetent thigh perforating veins present at the time of the first operation or did they occur afterwards? Would stripping of the long saphenous vein have prevented a recurrence in the majority of these limbs? The early recurrences (from months to 3 years) in seven limbs suggest that at least in some patients the incompetent perforating veins could have been present at the time of the original operation. The late recurrences (10–16 years) in 12 limbs suggest that many perforating veins become incompetent a long time after the operation (*Table 2*). After stripping, incompetent thigh perforating veins associated with recurrent varices were found 13–34 years after the operation (13, 18, 21, 23, 28 and 34 years in six limbs). Although these data support the rationale that stripping the long saphenous vein in the thigh[4,17,18] will prevent early recurrence associated with incompetent thigh perforating veins, the definitive answer can only be obtained from prospective studies. In the meantime, the surgeon should be aware of the possible

presence of incompetent thigh perforating veins which may be multiple and occur at any level along the whole length of the medial aspect of the thigh.

Lower limb vein trauma: a long-term clinical and physiological assessment

The aim of this study was to assess the long-term clinical and physiological sequelae of lower limb venous trauma in a civilian practice. Twenty-six patients who had undergone surgery for lower limb venous trauma (median elapsed time 19·5 months) underwent assessment. Injuries had been sustained to the external iliac, common femoral, superficial femoral and popliteal veins in two, four, nine and eleven limbs respectively. Using clinical assessment, photoplethysmography recovery time, the presence of popliteal reflux and venographic evidence of thrombosis, the final outcome was graded as good, fair or poor. Fourteen patients had pedal oedema, including two with a postphlebitic limb. The overall photoplethysmography recovery time (mean and s.d.) was 20·6 (8·7) s in the injured and 32·1 (6·7) s in the non-injured limbs (P = 0·002). Patients with a venographically occluded vein had a shorter photoplethysmography recovery time than those in whom the vein was patent (13·4 (5·6) versus *21·6 (8·7) s; P = 0·07). Popliteal reflux was present in 12 injured limbs. Seven of 12 venograms performed on limbs with a vein repair had evidence of previous thrombosis. Vein ligation carried considerable morbidity and all end-to-end anastomoses initially failed. In retrospect, saphenous vein grafts were too narrow for the recipient veins and panel grafts might have been more appropriate. Overall 11 of 26 patients (42 per cent) had a poor result. The repair of choice is a saphenous vein patch for lesser injuries and a saphenous panel graft for major injuries. Vein ligation should be avoided unless another life-threatening injury demands priority.*

The management of injuries to the deep veins of the lower limb remains a challenge. The morbidity of routine vein ligation was appreciated only after Rich *et al.* published their analyses of the Vietnam Vascular Register[1–3] and, although most reports continue to advocate repair, some recent publications have reported minimal morbidity after vein ligation[4–6]. It has been suggested that this may be explained, in part, by the nature of the injury, for earlier publications predominantly report combat injuries[1–3,7] where the circumstances differ substantially from those in civilian practice[4–6,8–10]. A further explanation may be the lack of good follow-up data which is an acknowledged shortcoming in all these studies. This is a significant omission as the long elapsed period required for the development of the postphlebitic limb is well documented[11]. Follow-up data have not been provided in some studies[9,10,12–14] and are limited to the short term in others[8,15–17]. Many of the follow-up data available have been obtained indirectly (e.g. postal questionnaire[2,3]) and few patients have been personally assessed[5]. No study has attempted to assess physiological venous function although venography has been performed in some patients[4]. The aim of the present study was to assess long-term clinical and physiological functions after lower limb venous trauma in a civilian practice.

Patients and methods

The hospital records of patients admitted during 1980–87, inclusive, with a lower limb vascular injury were reviewed and patients who sustained a vein injury (excluding saphenous vein injury alone) were invited to attend the vascular laboratory. Details recorded included the patient's age, sex, the elapsed time between injury and assessment, mechanism of injury, the vessel injured, the repair undertaken and the use of adjuvant procedures such as temporary shunting, fasciotomy or postoperative anticoagulation. After clinical assessment the patients underwent photoplethysmography[18], popliteal and femoral vein Doppler reflux studies[19] and, whenever possible, contrast venography of the injured limb performed after the method of Rabinov and Paulin[20]. The patient's non-injured limb was used as his own control.

Using these results the outcome of the injury was classified as good, fair or poor, and when the category was uncertain the better result was assumed (*Table 1*). If a surgically correctable lesion was identified the patient was offered reconstructive surgery[1]. Statistical analysis was by the Student's *t* test. The study was approved by the University of Cape Town Ethical Trials Committee and the patients undergoing venography gave informed consent.

Results

We were able to contact 26 of 48 patients who had undergone surgery for a lower limb vein injury during the study period; all attended the vascular laboratory and they form the basis of this report (*Table 2*). Five of the remaining 22 patients could not be assessed; two patients died in the early postoperative period from associated injuries and two patients required amputations for extensive soft tissue injuries. The popliteal vein in another patient was noted to be thrombosed when the

popliteal artery required re-exploration 10 days after an end-to-end repair of both the vein and artery.

The median age at the time of surgery was 26 years (range 11–51 years) and the median elapsed time from injury to assessment was 19·5 months (range 0·5–66 months). Twenty-five patients were men and had injuries sustained by gunshot (15 patients), stab (6 patients) or major blunt trauma (4 patients). The single woman had an iatrogenic injury during varicose vein surgery.

The repairs undertaken are detailed in *Table 3*. Two patients had a temporary arterial shunt inserted while the vein was repaired and 12 patients, of whom only one had an isolated vein injury, required an adjuvant fasciotomy. In the immediate postoperative period five patients received postoperative subcutaneous heparin 5000 units, 8- or 12-hourly, and one received low molecular weight dextran.

Two of three patients in whom the popliteal vein was ligated required urgent re-exploration within 12 h of surgery for severe limb-threatening oedema[2]. One then had an end-to-end anastomosis of the vein and the other a fasciotomy only. Two years later the latter patient required vein reconstruction for a chronically swollen leg. Clinical oedema also developed in both the superficial femoral veins and the single external iliac vein that had been ligated (*Tables 3* and *4*). On examination, 14 patients had dependent pedal oedema (*Table 4*) of whom 13 had abnormal venous function. Two of three patients in whom the popliteal vein had been ligated had an established postphlebitic limb. Twelve patients had no pedal oedema but four had abnormal venous function and continue to be observed.

Photoplethysmography was performed in all 26 patients. An abnormal photoplethysmogram upon which no meaningful interpretation could be performed was recorded in three patients in whom the vein had been repaired (three injured limbs and two non-injured limbs). The overall photoplethysmography recovery time (mean and s.d.) was 20·6 (8·7) s in the 23 injured limbs and 32·1 (6·7) s in the 24 non-injured limbs ($P = 0{\cdot}002$). The photoplethysmography recovery times of those having venography are shown in *Figure 1*. Popliteal venous reflux was found in 12 injured limbs. None of the non-injured (control) limbs had oedema or Doppler reflux.

Ascending venography was performed in 17 patients. The vein was occluded in 11 patients (*Figure 1*); the vein had been ligated in six and thrombosed in five. Nine of the 11 limbs shown on venography to have an occluded vein had oedema with abnormal function. Two of the 11 limbs were without oedema: one had abnormal function and one normal function. Extensive venous collaterals were found in all six limbs in which the vein had been ligated and five had developed oedema which was associated with abnormal function (*Figure 2*). The vein was patent in six patients. Five had no evidence of oedema, but three had associated abnormal function, and the sixth limb had a patent vein with oedema and abnormal function. Twelve limbs that had undergone vein repair had a venogram and seven (58 per cent) had evidence of previous thrombosis.

The 17 patients who underwent venography were subdivided in two groups depending on whether the deep veins were patent (six patients) or thrombosed (11 patients; *Figure 1*). The three patients with abnormal photoplethysmography underwent venography and although the non-injured vein was normal the injured vein had thrombosed in all three. Thus in the thrombosed group only eight injured and nine non-injured limbs were available for assessment. The photoplethysmography recovery time (mean and s.d.) in the injured limbs was significantly shorter than in the non-injured limbs in both those with a thrombosed vein (13·4 (5·6) *versus* 32·2 (10·6) s, $P = 0{\cdot}001$) and those with a patent vein (21·6 (8·7) *versus* 35·0 (4·5) s, $P = 0{\cdot}004$; *Figure 1*). The photoplethysmography recovery time in the injured limbs with a thrombosed vein on venography was shorter than in those with a patent vein but this difference was not significant (13·4 (5·6) *versus* 21·6 (8·7) s, $P = 0{\cdot}07$).

Our assessment of the final outcome is shown in *Table 5*. One patient with a poor/fair outcome was placed in the fair group.

Discussion

This study has two principal conclusions. Firstly, that in the long term 58 per cent of the repaired veins thrombosed and, secondly, even after successful repair, as demonstrated by a patent vein on venography, there may be serious physiological

impairment of venous function when assessed by photoplethysmography. Patients thus affected, who are often young men, may then be at risk of subsequent development of a postphlebitic limb, an essentially incurable chronic disability that causes much social, economic and physical hardship[21]. This study has also confirmed the harmful consequences of popliteal vein ligation and suggests that ligation of the proximal lower limb veins is associated with appreciable clinical morbidity and abnormal physiological function.

These new observations are important because previous studies, which have not always concluded that repair is necessary[4–6], arrived at their conclusions without the benefit of any follow-up[9,10,13,14] or after only short follow-up[7,15–17] unaided by either venographic or physiological assessment[4,5]. We believe that adequate assessment in either the short or long term can be obtained only if it includes both venography to determine patency and physiological tests to measure function. Laboratory evaluation may identify those patients likely to develop a postphlebitic limb at an earlier stage and permit careful follow-up. Although photoplethysmography is simple, non-invasive and easy to repeat, the muscle pump may not be normal following fasciotomy and we are currently assessing photoplethysmography after fasciotomy.

The surgeon has two goals when approaching vein injuries. The first is to ensure the limb survives the acute trauma and the second is to restore long-term venous function. That individual, injured lower limb veins can be ligated without immediate serious sequelae has never been denied but what has been debated is the wisdom of adopting ligation as the preferred strategy. Limb loss has been reported following popliteal vein ligation[1,9,13] and we believe the evidence in the literature, supported by this study, demonstrates that popliteal vein ligation is not acceptable unless an associated life-threatening injury demands priority. The acute consequences of proximal vein ligation appear to be less serious, presumably due to the development of more extensive collaterals, but this has not been adequately studied. In the present study, patients in whom the superficial femoral vein (two patients) or the external iliac vein (one patient) was ligated had oedema and abnormal function tests.

The only disadvantage of venous repair is the time required to execute the repair and possibly the only indications for venous ligation are complex lacerations or associated injuries that require priority. Those who advocate vein ligation argue that early thrombosis frequently occurs following vein repair and that within a few days sufficient collaterals will have developed to ensure limb survival[7,16]. We have shown that, even after the development of extensive collaterals, vein function generally remains abnormal even though the immediate catastrophe of limb-threatening oedema or venous gangrene is avoided. Combined arterial and venous injuries are more serious than venous injuries alone[1,16,22] and the normal revascularization oedema that follows limb ischaemia must be aggravated when the vein is ligated. Although it has been suggested that if the vein thromboses after a repair the risk of a subsequent pulmonary embolus is increased, there is little evidence to support this.

To reduce the 60 per cent thrombosis rate in this and other studies[17,22], perioperative care must be meticulous. Minor injuries may be repaired by lateral venorrhaphy but in the present series venography revealed that the lumen was often

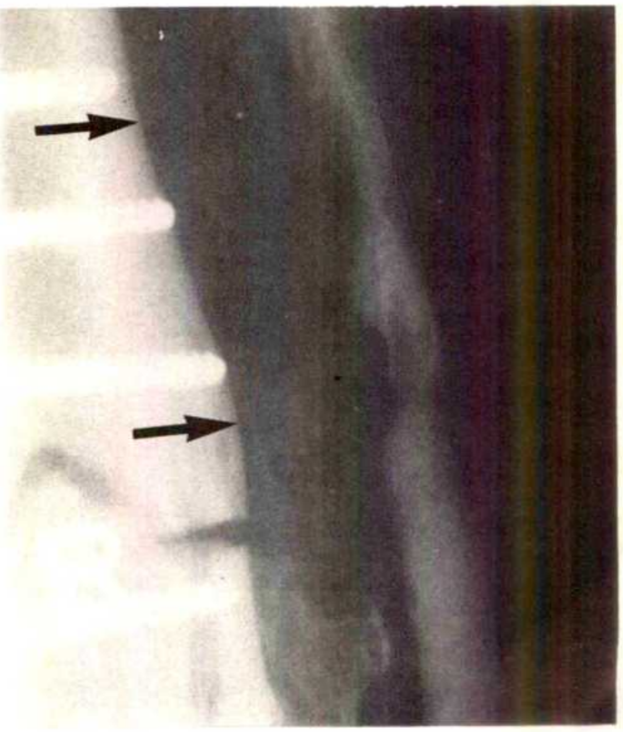

Figure 3 *Venogram of a superficial femoral vein repaired with a panel graft. There were no collaterals and the patient remains asymptomatic*

narrowed by this technique and if there has been any tissue loss a vein patch should be used. In all major injuries a saphenous vein graft from the opposite limb should be harvested but, in our experience and that of others, the donor vein is often too narrow for direct use and a panel graft must therefore be fashioned (*Figure 3*)[9,10]. End-to-end anastomosis in our hands had a poor outcome, probably because it was performed when a panel graft should have been inserted, although others have had greater success[17].

The minimum time between injury and restoration of blood flow is critical for limb survival[11] and insertion of an arterial shunt will permit temporary restoration of limb perfusion. When there is a combined arterial and venous injury or bilateral injuries, a shunt will permit arterial perfusion while the vein or opposite limb is repaired. In this study the median elapsed time from injury to restoration of arterial blood flow was over 7 h. Fasciotomy should be readily performed and probably routinely performed in limbs with a combined injury or injury to the popliteal vein[5,9,16]. The importance of other perioperative techniques such as postoperative limb elevation, arteriovenous fistulae, stockings and long-term anticoagulation with warfarin remains unproved but they are all theoretically attractive[6]. Five of our patients received low dose heparin and one received dextran in the early postoperative period and this may help to decrease the incidence of postoperative thrombosis. Three patients had a good result and the remaining repairs failed for technical reasons (i.e. a small saphenous vein graft). Experimentally, low molecular weight dextran has been shown to be superior to heparin[23].

Lower limb deep vein injuries remain a surgical challenge[24] but their management is no longer controversial[9,17]. Vein repair with either vein patch or a panel graft should be attempted in all patients unless other life-saving procedures require priority.

To evaluate the prevalence of abdominal aortic dilatations among asymptomatic brothers and sisters of patients with abdominal aortic aneurysms (AAAs), an ultrasonographic screening study was performed. One hundred and two siblings of patients operated on for AAAs at two Swedish hospitals were invited to attend, and 87 of them (35 men and 52 women) from 32 different families, accepted the invitation. Their median age was 63 years (range 39–82 years). Aortic dilatation was diagnosed in ten of the brothers (29 per cent) and three of the sisters (6 per cent). In ten cases (eight men and two women) there was a localized dilatation caudal to the coeliac axis, and in three a general dilatation of the abdominal aorta with the diameter at the coeliac axis > 29 mm. None of the aortic dilatations had been known before this study was performed. The conclusion is that the prevalence of asymptomatic aortic dilatations among brothers of patients with AAAs seems to be high and that this group should be selected for further screening studies.

Keywords: Abdominal aortic aneurysms, ultrasonographic diagnosis

Abdominal aortic aneurysms (AAAs) are responsible for about 1·3 per cent of the deaths among men aged over 50 years both in the UK and in Sweden, and the proportion has been increasing[1,2]. The true mortality rate from ruptured AAAs is as high as 85–95 per cent when both the subjects operated on and those not operated on are included[3–5], while the rate at elective operations is < 5 per cent in many centres[6–8]. To reduce the total mortalities, it is necessary to increase the percentage diagnosed and operated on electively. However, many of the AAAs are more or less asymptomatic[2,9], and the only way to diagnose these aneurysms before rupture is by screening. Screening of the whole population is unrealistic because of the costs in money and other resources[10], but, if defined groups with a high prevalence could be found, screening of these groups might be more cost effective.

One group that may be a potential target for a screening programme are siblings of patients with AAAs. Clinically apparent AAAs are common in this group[11–14], but nothing is known about the prevalence of asymptomatic AAAs. The purpose of the present study was to investigate the prevalence of previously unknown aortic dilatations among siblings of patients operated on for AAAs.

Patients and methods

The study was based on brothers and sisters of 84 patients (66 men and 18 women) who had been operated on for AAAs at two Swedish hospitals during the years 1981–86, and who were still alive on 1 September 1987. Twenty-nine of the operations had been performed at the Department of Surgery, University Hospital of Umeå, in the northern part of Sweden, and 55 at the Department of Surgery, Malmö Allmänna Sjukhus, University of Lund, in the southern part of Sweden. Information about the patients was obtained from the hospital register. A questionnaire was sent to the 84 patients requesting the names and the addresses of all their brothers and sisters who were still alive. Eighty-one patients (96 per cent) answered the questionnaire, and 159 of their brothers and sisters (60 brothers and 99 sisters) were still alive. However, in 57 cases (15 brothers and 42 sisters) these siblings were living abroad or far away from the investigating centres, and they were excluded. The remaining 102 siblings (45 brothers and 57 sisters) were invited to attend, and 87 (35 brothers and 52 sisters) accepted the invitation (85 per cent).

The median age of the attenders was 63 years (range 39–82 years), with no sex difference. They were from 32 different families, 13 from the area of Umeå with 42 siblings, and 19 from the area of Malmö with 45 siblings. The number of examined siblings in each family was one in 12 cases, two in eight cases, three in three cases, four in four cases, five in one case, six in two cases, eight in one case and nine in one case.

The siblings attending the study were fasted for at least 4 h before the examination. The examination of the aorta was in all instances performed by ultrasonography, using real-time equipment. The abdominal aorta was examined throughout its length, and the external diameter perpendicular to its length axis was registered at the level of the coeliac axis, just cranial to the aortic bifurcation and, when there was a localized dilatation caudal to the coeliac axis, at the level where the diameter was maximal. Aortic dilatation was defined as a localized dilatation of the abdominal aorta caudal to the level of the coeliac axis and/or an abdominal aorta > 29 mm in maximal diameter at the level of the coeliac axis. The examinations, by radiologists experienced in ultrasound techniques, were performed in 25 cases in Umeå, in 46 cases in Malmö, and in 16 cases at seven hospitals surrounding Umeå.

The attenders were asked about smoking habits, previous myocardial infarctions, cerebrovascular lesions and operations, whether they were taking antihypertensive drugs, and whether they were suffering from diabetes mellitus. The subjects examined in Umeå or Malmö had a general physical examination, including body weight and height, auscultation of peripheral pulses, and registration of blood pressure in both arms and in the ankles. The χ^2 test was used to test differences in proportions between groups, with Yates' correction when samples were less than five, and the two-tailed Mann–Whitney U tests were used to ascertain differences between groups concerning ordinal observations. P values $< 0{\cdot}05$ were considered as statistically significant.

Results

Abdominal aortic dilatation was found in ten brothers and three sisters. The frequency among the brothers was 29 per cent (95 per cent confidence interval 14–44 per cent), and among the sisters 6 per cent (95 per cent confidence interval 0–12 per cent). Ten of the affected siblings, eight men and two women, had a localized dilatation of the abdominal aorta caudal to the coeliac axis, with maximal diameters of 28 (woman), 33, 35, 36 (woman), 36, 37, 37, 42, 56 and 65 mm. The diameters at the coeliac axis in the same patients and in the same order are 20,

0007-1323/89/060589-03$3.00 © 1989 Butterworth & Co (Publishers) Ltd

28, 26, 25, 24, 20, 23, 17, 24 and 26 mm. The other three affected siblings, two men and one woman, had a general dilatation of the abdominal aorta, with maximal diameters of 33 (woman), 33 and 34 mm at the level of the coeliac axis. The mean (s.d.) diameter of the aorta of those without aortic dilatation was 22·2 (3·2) mm at the level of the coeliac axis, and 17·0 (2·7) mm just cranial to the aortic bifurcation.

The median age of the affected brothers was 62 years (range 49–73 years), and the ages of the three affected sisters were 61, 71 and 74 years. The siblings with aortic dilatation did not differ in age from those without ($P = 0·99$). Eleven of the brothers in the study were less than 60 years of age, and in this group four had aortic dilatation. The youngest affected sibling was a 49-year-old brother with a localized dilatation of the abdominal aorta.

Three of the affected siblings (two men and one woman) were of the same family, in which six siblings were examined, while the other ten were from ten different families. Six subjects with aortic dilatation (five men and one woman) were found among the siblings from Umeå, and seven (five men and two women) among those from Malmö. All the diagnosed aortic dilatations were asymptomatic and had not been known before this study was performed.

Nine of the siblings with aortic dilatation (69 per cent), but only 16 of those without (22 per cent), were taking antihypertensive drugs. This difference is statistically significant ($P < 0·001$). Both systolic ($P = 0·02$) and diastolic ($P = 0·03$) blood pressure (with eventual antihypertensive drugs) was significantly higher among the 13 subjects with aortic dilatation than among 64 subjects without. The ankle:arm blood pressure index was below 1·0 in six out of 70 examined siblings, and two of these (one man and one woman) had aortic dilatation. Seven siblings, all of them men, had been treated for myocardial infarction. Five of the ten men with aortic dilatation, but only two of the 25 men without, had had myocardial infarction. This difference is statistically significant ($P = 0·01$). Two siblings, one man and one woman, suffered from diabetes mellitus, but they did not have aortic dilatation. Ten of the siblings with aortic dilatation (77 per cent), and 40 of those without (54 per cent) were smokers. This difference is not statistically significant ($P = 0·47$). The men with aortic dilatation were not statistically taller ($P = 0·73$) or heavier ($P = 0·081$) than those without.

Discussion

The purpose of the present study was to evaluate the prevalence of aortic dilatation among living brothers and sisters of patients operated on for AAAs, and therefore no effort was made to get information about clinically diagnosed and ruptured AAAs among the deceased brothers and sisters. However, one of the brothers, who was still alive, had been operated on for an AAA.

The study was retrospective in the sense that the siblings were not registered at the time of aortic surgery. Fifty-seven siblings were excluded for geographical reasons, but this did not influence the representiveness of the sample. Fifteen siblings refused examination, but both the proportion of men and the median age was higher in this group than among the attenders, and there is therefore no reason to suspect a lower prevalence of aortic dilatation in this group. As far as we know, none of the attenders had any symptoms making them more prone to attend than others.

Ultrasonography was used to examine the aorta; it is a well established method[15–17]. All the ultrasonographic examinations were performed by radiologists experienced in ultrasound techniques; therefore the prevalence of aortic dilatations was not caused by misinterpretation of the findings. The definition of aortic dilatation that was chosen is based on the diameter of the normal abdominal aorta which decreases from the level of the coeliac axis caudally[18]; the upper limit of normality of the diameter at the coeliac axis has been proposed to be 29 mm[18–19].

Little is known about the prevalence of aortic dilatation in the population, and only three ultrasonographic studies have been published. Scott and Ashton[20] found 2·7 per cent (95 per cent confidence interval 1·5–4·0 per cent) aortic dilatations, defined as an abdominal aortic diameter >35 mm, in a group of men and women aged 65–85 years[20]. If the same definition was used in the present study, 17 per cent of the brothers (95 per cent confidence interval 4·7–29·6 per cent) would have had aortic dilatation. Collin *et al.*[21] found 3·4 per cent aortic dilatation (95 per cent confidence interval 1·2–6·7 per cent), defined as a diameter exceeding 32 mm, in a group of men aged 65–79 years[21]. The latter study could be compared with our results because the aortic dilatation among men in our study had a diameter >32 mm. The prevalence among the men in our study was 29 per cent. Collin *et al.*[22] have recently published another screening study of 426 men aged 65–74 years. In their study AAA was defined as an infrarenal aortic diameter >39 mm or exceeding the suprarenal aortic diameter by at least 5 mm. They found 5·4 per cent with AAAs (95 per cent confidence interval 3·3–7·5 per cent). With the same definition in the present study 23 per cent of the brothers (95 per cent confidence interval 8·9–36·8 per cent) had AAAs.

The occurrence of clinically diagnosed and ruptured AAAs among the deceased and living blood relatives of patients with AAA has been investigated in at least four studies. In one of these the incidence among the brothers and sisters of the patients was 1·9 per cent[11], and in another one it was 7·3 per cent[14]. In a third study, where the family histories of AAA-patients and controls were compared, AAAs were 11·6 times more common among the first degree relatives (brothers, sisters, parents, children) of the patients[13]. These figures are not directly comparable with the figures in the present study, because we were investigating the prevalence of aortic dilatations among asymptomatic siblings, but they show that familial aggregation of AAAs exists. A multifactorial mode of inheritance has been proposed, with at least one gene on the X chromosome[11–14]. This has been supported by studies of genetic markers and serum levels of lipids which, to some extent, are genetically determined[23–27].

In the studies concerning clinically diagnosed AAAs in the family the most common pattern was that only one blood relative was affected apart from the proband, but instead a high proportion of the probands had affected siblings[11,13,14]. In the present study 11 out of 32 probands (34 per cent) had siblings with aortic dilatations, and in ten of these families only one brother or sister was affected. On the other hand only one or two siblings from each family were examined in most of the families in the present study. More extreme families have also been described. In a study based on reports from several centres in the USA, Tilson and Seashore[12] described families with up to six affected siblings, with affected siblings from three generations, and with affected identical twins. In one of the families in the present study three out of six examined siblings had aortic dilatation, apart from the proband.

Comparison with other ultrasonographic screening studies of risk groups concerning the prevalence of aortic dilatation indicates that the prevalence is higher among brothers of patients who have had aneurysm surgery than among patients with various atherosclerotic manifestations or hypertension[28–33].

The prevalence of AAAs increases with age[34,35]. In our study there was no difference in age between those with and those without aortic dilatation. The blood pressure was higher among those with aortic dilatation than among those without, and a history of drug-treated hypertension was also more common in the first group. This is in agreement with the results of other studies[30]. Myocardial infarction was more common among the men with aortic dilatation than among those without, and this is also in accordance with other studies[25,36].

In conclusion the prevalence of asymptomatic aortic dilatation among the brothers of AAA-patients seems to be high, and this group must be considered for further screening programmes. Before more firm recommendations can be made, it is necessary to evaluate the prognosis of the aneurysms and dilated aortas discovered in screening studies, and to evaluate the cost effectiveness of such screening.

Mr A. E. Clason

Surgical audit data for two 5-year periods (1974–78 and 1983–87) have been compared in a Health Board Area to assess the impact of centralization of emergency vascular services on the treatment of the acutely ischaemic lower limb. Patient populations in each period were comparable. Mortality rates remained constant in both periods at approximately 30 per cent. A significant improvement in overall limb salvage was observed (from 54 to 67 per cent, $P < 0{\cdot}05$*). Limb salvage in survivors was improved from 80 to 95 per cent (*$P < 0{\cdot}001$*) and was paralleled by an increase in the number of reconstructive vascular procedures performed. We concluded that the centralization of emergency vascular services has not led to a reduced risk of mortality but has been associated with improved limb salvage.*

Keywords: Acute lower limb ischaemia, morbidity, mortality, centralization

The recent Report of the Confidential Enquiry into Perioperative Deaths (CEPOD) has highlighted the provision of emergency care for vascular disease as a problem area and a cause for concern[1]. In the UK, vascular surgery is not yet recognized as a separate speciality. The majority of vascular procedures are performed by general surgeons with variable vascular training and many other demands on their time. Few areas offer a regionalized service staffed by surgeons who work exclusively in the field. Increasing vascular workloads are reported[2,3] and the greater longevity among the population makes it likely that this trend will continue. The management of the acutely ischaemic limb, although revolutionized by the advent of the balloon embolectomy catheter[4], remains problematical. The operation of thromboembolectomy is a relatively simple procedure, but is still followed by high amputation and mortality rates. A vascular surgical unit providing a supra-area vascular emergency service for the three Health Board areas of south-east Scotland was formed in Edinburgh in 1982. The purpose of this study was to assess the impact of centralization of vascular services on the outcome of the acutely ischaemic lower limb.

Patients and methods

Two separate 5-year periods were examined: the period 1974–78 when vascular services were provided largely by general surgeons, and the period 1983–87 after the establishment in 1982 of a regional vascular service manned by three consultant vascular surgeons and their junior staff. During the period 1978–82 there was an increasing trend in Edinburgh towards centralization of vascular services. Whilst the majority of vascular emergencies were handled by the unit destined subsequently to provide an integrated supraregional service, a substantial number of cases were managed by general surgeons with varied experience of vascular surgery. In contrast, from 1982 all vascular emergencies in south-east Scotland (population approximately $1{\cdot}2 \times 10^6$) were referred to the new unit at the Royal Infirmary of Edinburgh. The period 1974–78 was chosen because it was considered most representative of a time period before the centralized service was available.

Patients admitted with acute lower limb ischaemia were identified from unit statistics assembled annually for the Lothian Surgical Audit. For the first 5-year period the audit data were prospectively collected and hand processed by individual units. During the second 5-year period all operative procedures were prospectively recorded and identified by a computerized coding system[5]. Identified cases were checked against operation record books and individual case notes and the relevant data extracted. The Audit includes details of all deaths on surgical units whether or not the patients had an operation. No alteration in patient management occurred between the two study periods. Patients with occlusive events following trauma or after previous arterial reconstruction were not included.

Patients were either given heparin and underwent emergency thromboembolectomy using a standard balloon catheter technique, or were treated conservatively with heparin or streptokinase, unless the limb was clearly irrecoverable or the patient moribund on admission.

Results

Approximately 45 patients with an acutely ischaemic limb were referred for emergency treatment per annum, representing an incidence of 1:27 000 population. The patient characteristics in the study period (1983–87) and the reference group (1974–78) were similar (*Table 1*), with approximately 90 per cent coming to operation. In the earlier period 85 per cent of the operations were performed under local anaesthesia in contrast to 96 per cent in the later study period. Roughly similar distributions of emboli were encountered during both periods and more proximal lesions were associated with a higher mortality rate. Similar proportions of the study groups had cardiac arrhythmias or recent myocardial infarction as a likely source of embolism, and similar proportions of each group had evidence of pre-existing atherosclerotic arterial disease with a past history of intermittent claudication or absence of contralateral limb pulses on clinical examination.

Profundaplasty	0	2
Angioplasty	0	1
Total	4	23

Incidence of reconstructive procedures (Table 2)

Twenty-three patients in the second study period had additional vascular operative procedures performed in conjunction with embolectomy, of whom three died and a further two required a major limb amputation. Only four such procedures were undertaken in the earlier period and all were performed in patients admitted to general surgical units in which a surgeon with a vascular interest happened to be located.

Outcome (Table 3)

The mortality rates in both study periods were comparable at approximately 30 per cent although the range of mortality rates for individual units varied considerably (26–43 per cent) in the earlier period. However, overall limb salvage was significantly better in the later period (1983–87) than in the earlier period (1974–78): 67 *versus* 54 per cent, $\chi^2 = 5{\cdot}88$, $P < 0{\cdot}05$. Furthermore limb salvage in survivors showed an even more significant improvement (95 *versus* 80 per cent, $\chi^2 = 13{\cdot}8$, $P < 0{\cdot}001$) between the two periods and parallels the increase in the number of reconstructive procedures. It was also noted that the limb salvage rate for patients treated in a unit with a vascular interest improved from 57 to 67 per cent.

Discussion

The fact that the study periods were almost a decade apart is an obvious imperfection in the comparison. Nevertheless, there has been little change in the surgical management of acute lower limb ischaemia, embolectomy with a balloon catheter remaining the standard approach over the last 25 years. Improvements in patient care over the last decade, if significant, might be expected to have improved not only limb salvage rates, but also mortality. This did not occur. Previous studies[5,6] have indicated that the outcome of vascular operations depends principally on the judgement and experience of the individual surgeon and is not predictable purely on the basis of hospital size and workload. This appears to be confirmed by the appreciable improvement in morbidity and mortality rates after emergency aneurysm surgery in centralized vascular surgical units[7,8]. In the present study no corresponding improvement in mortality has been found in the management of acute lower limb ischaemia. The continuing high mortality rate confirms the recent experience of Galbraith *et al.*[9] where in a comparable population 42 per cent either died or required major limb amputation following thromboembolectomy. In the present study similar patient characteristics were found in both study periods, with the same proportion of high risk individuals, and so it may be inferred that mortality largely reflects concurrent disease in this aged population[10]. However, the morbidity (as measured by the overall limb salvage rate) shows a significant improvement. This must nevertheless be interpreted with a degree of caution for, whilst overall limb salvage rate improved from 54 to 67 per cent over the 9-year period, limb salvage in units with a vascular interest also improved from 57 to 67 per cent, perhaps partly attributable to increased exposure and earlier referral of such patients to the centralized service. As the vast majority of vascular emergencies in south-east Scotland are now handled by the new supraregional secondary referral service, analysis of its impact on the outcome of acute lower limb ischaemia can only be retrospective.

Table 3 *Outcome of the patients treated during the two time periods*

	1974–78	1983–87
Number of patients	218	204
Total limbs at risk	252	234
Conservative treatment	28	21
Non-operative deaths	11	9
Hospital death without gangrene	13 (6)	14 (7)
Hospital death with gangrene	58 (27)	48 (24)
Overall limb salvage	118 (54)	135 (67)
Units without vascular interest	66/127 (52)	—
Units with a vascular interest	52/91 (57)	—
Overall limb salvage in survivors	118/147 (80)	135/142 (95)
Units without vascular interest	66/86 (77)	—
Units with a vascular interest	52/61 (85)	—
Overall mortality	71 (32)	62 (30)

Figures in parentheses are percentages

Not all acutely ischaemic lower limb problems can be solved by balloon catheter thromboembolectomy alone, as a significant proportion may be secondary to pre-existing atherosclerosis and may require vascular reconstruction. The improvement in limb salvage rates may reflect the increased number of immediate vascular reconstructions performed in the later period (18 of the 23 patients who underwent a reconstructive procedure survived with both limbs intact). It is in this latter area that the advantage may lie of concentrating experience in a specialized service. With the generally accepted high cost of amputation and consequent care, it is possible that the extra expense of transportation incurred by the centralization of the treatment of acute lower limb ischaemia is more than balanced by the improvement in limb salvage.

If the 13 per cent improvement in limb salvage were generally applicable (with an incidence of 1 in 21 000) then it would suggest that approximately 300 amputations resulting from acute ischaemia could be avoided each year in the UK. However, this too may be an underestimate as the continuing loss of limb and high mortality rate in our unit suggest that we need to review critically our methods of treating acute lower limb ischaemia.

Professor H. H. Lawson

Both penetration and perforation of the capsule were seen on the superficial aspect of pleomorphic adenomas. Only penetration was noted on the deep aspect, where the tumour was adjacent to the facial nerve. In terms of local recurrence this may explain why it appears to be safe to separate the deep aspect of the tumour from the facial nerve without a wide margin of normal parotid tissue.

Keywords: Pleomorphic adenoma, capsule, recurrence

It is well recognized that after the simple procedure of enucleation, there is a recurrence rate of pleomorphic adenoma that varies from 20 to 45 per cent in the reported cases[1–3]. After wide excision with preservation of the facial nerve, recurrence rates from 0 to 2·5 per cent are reported[4–6]. In a recent series of 130 wide excisions for pleomorphic adenoma, followed up for a maximum period of 20 years, there was a single recurrence only[7]. In their important contribution, Patey and Thackeray[8] clearly showed what they termed 'focal infiltration' of the capsule, and demonstrated how pseudopodia of the tumour could be left behind if the lesion was enucleated. It is generally accepted that this is the explanation for tumour recurrence and the justification for the standard procedure of wide excision with preservation of the facial nerve.

The procedure of wide excision seems to work well in terms of avoiding tumour recurrence, even in very large tumours when the deep surface of the tumour impinges against the facial nerve. In these cases the nerve may be adherent to the tumour, from which it can only be separated with considerable difficulty. Certainly there is no macroscopically normal tissue between the nerve and the tumour.

Other authors have made the same observations with regard to large tumours, but have offered no explanations[5,6]. Hancock[6] has been so influenced by this observation that he now advocates removal of the tumour with only a covering of normal parotid tissue, and his reported recurrence rate over a follow-up period of 4 years is 1·6 per cent.

If the phenomenon of focal infiltration, or pseudopodia formation, was the only explanation for recurrence, why is there not a high rate of recurrence from tumour left in the region of the facial nerve after the removal of these large tumours?

The object of the present study was to compare the histopathology of the capsule on the deep surface of the tumour, where it was adjacent to the facial nerve, with the histopathology of the capsule on the superficial surface of the tumour, where it lay adjacent to normal parotid tissue.

Patients and methods

Seven patients, all with large lesions, greater than 5 × 7 cm clinically, underwent superficial parotidectomy for histologically confirmed pleomorphic adenoma of the superficial lobe of the parotid gland. The specimens were bisected in the sagittal plane into a deep and superficial part (*Figure 1*, line A–B). The superficial part of the capsule was defined as that part of the capsule lying on the superficial surface of the tumour between the tumour and normal parotid tissue (*Figure 1*,1). The deep part of the capsule was defined as that part of the capsule adjacent to the facial nerve (*Figure 1*,2). Multiple sections, and where necessary serial sections, were prepared in the horizontal plane above and below the lines C–D and E–F in *Figure 1*. All material was divided immediately after resection in this way and was fixed in 10 per cent formol saline. Using routine histological techniques and stains, the specimens were examined by conventional light microscopy.

Results

The superficial part of the capsule (Figure 1,*1*)

Two types of capsular involvement were observed and were present in all seven specimens.

1. *Capsular penetration*: an example is illustrated in *Figure 2*. The tumour can be seen as a nodular protrusion into the capsule, but at no point was there any disruption of the actual capsule between the tumour and normal parotid tissue. This observation was confirmed by serial section examination of the capsule over the whole area of the nodule.

2. *Capsular perforation*: this is illustrated in *Figure 3*. The tumour has clearly perforated through the whole thickness of the capsule, and can be seen lying adjacent to the normal parotid tissue.

Capsular penetration, which must obviously precede capsular perforation, was seen more frequently than perforation, and in many sections only penetration occurred. Where both features were seen in a single slide, with a capsule length of 300–400 mm, it was usual to see about five examples of penetration, and two or three examples of complete perforation. Capsular involvement did not occur in all sections, and could be missed if only limited material were examined.

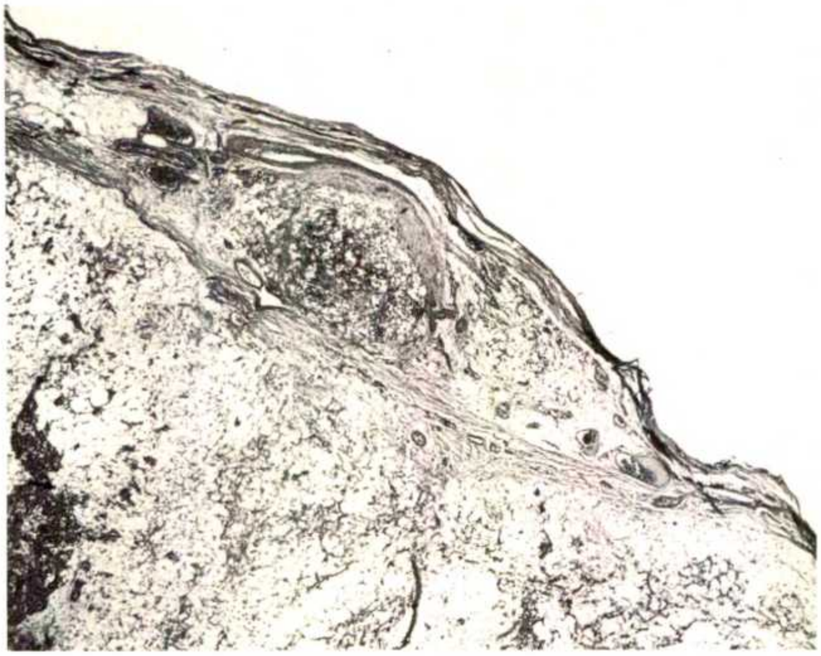

Figure 2 *Capsular penetration: the capsule superficial to the lesion is intact* (×25)

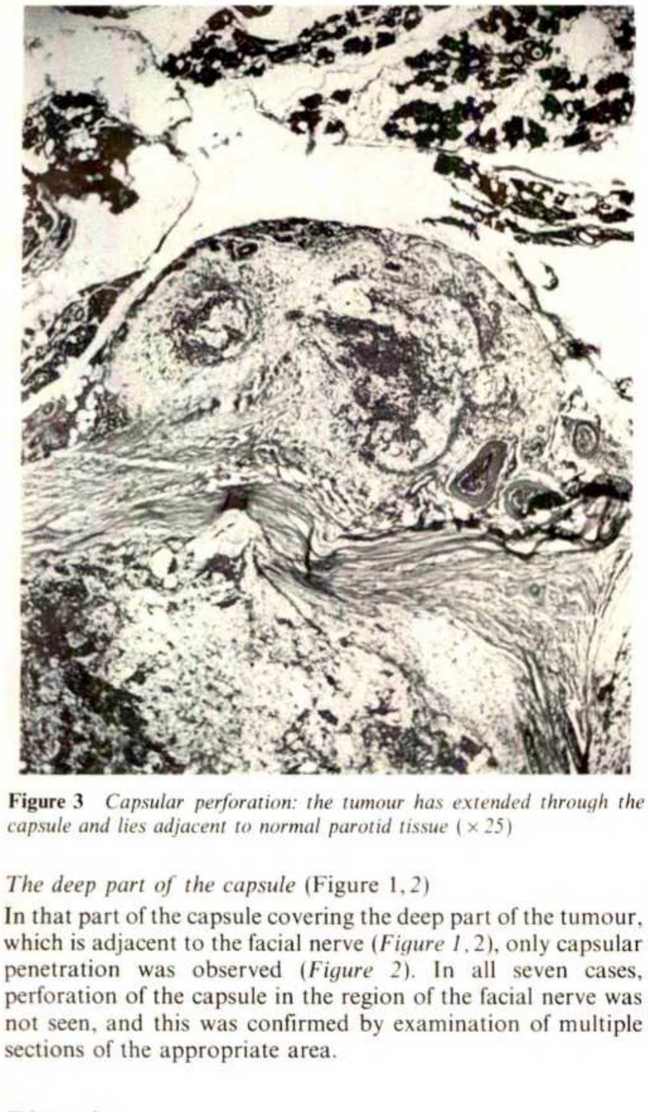

Figure 3 *Capsular perforation: the tumour has extended through the capsule and lies adjacent to normal parotid tissue* (×25)

The deep part of the capsule (Figure 1, *2*)

In that part of the capsule covering the deep part of the tumour, which is adjacent to the facial nerve (*Figure 1, 2*), only capsular penetration was observed (*Figure 2*). In all seven cases, perforation of the capsule in the region of the facial nerve was not seen, and this was confirmed by examination of multiple sections of the appropriate area.

Discussion

A description of the histopathology of pleomorphic adenoma would not be relevant in the present paper. An authoritative description has been given elsewhere[9]. Where the capsule is perforated by tumour (*Figure 3*) it is very likely that enucleation in the plane between its capsule and normal parotid tissue would result in incomplete removal of the tumour. Removal of the whole lesion could only be achieved if sufficient normal parotid tissue were removed at the same time. Where only capsular penetration is present (*Figure 2*), it is likely that enucleation in the same plane, i.e. between the tumour capsule and normal parotid tissue, would be successful in removing all the lesion.

In the present study, the only type of capsular involvement seen on the deep surface of the tumour was capsular penetration. Provided there was no breach of the capsule, this would offer an explanation for the observation that in the standard procedure of wide excision in large tumours, recurrence does not seem to occur as a result of tumour being left behind in relation to the facial nerve.

Where penetration of the capsule by the tumour has occurred, it has been pointed out that the phenomenon of subcapsular splitting, i.e. a split in the tumour lying within the capsule, may occur, while the capsule itself remains intact. If the surgeon entered this area inadvertently, this could be another reason for incomplete removal[8].

It is most unlikely that capsular perforation never occurs on the deep surface of the tumour in relation to the facial nerve, although it was not seen in the present study, which was limited to seven specimens. However, it does seem that it is at least an uncommon occurrence. The explanation for the observation is completely speculative. It is possible that capsular perforation is inhibited because of the very small restricted anatomical area of the parotid bed, bounded, as it is, anteriorly by the bone of the ramus of the mandible, posteriorly by the mastoid process, and above by the petrous temporal bone. The styloid process with its muscle and ligaments may provide a medially situated mechanical barrier.

The lack of any type of mechanical restraint in small peripheral tumours may allow capsular perforation to occur circumferentially around the whole tumour, which may explain the frequently quoted observation that recurrence seems to occur more often when small tumours are removed[3]. The same author writing in 1936 advised that the surgeon should wait until the 'tumour (is) ripe, that is about the size of a lemon'[3]. An increased frequency of focal infiltration of the capsule in small tumours has been recorded by others[8]. Even in large tumours, as in the present study, perforation of the superficial part of the capsule occurs; this was the case in all of the seven specimens examined here. The correct surgical procedure for the management of small or large pleomorphic adenomas of the parotid would therefore seem to be the standard operation of wide excision of the tumour with preservation of the facial nerve. The excellent results reported by Hancock[6], where less parotid tissue was removed, should be noted, although the follow-up period in that series is still relatively short.

Correspondence to: Dr M. I. Kairaluoma

It has been suggested that preoperative localization of enlarged parathyroid glands by ultrasound would facilitate neck exploration for primary hyperparathyroidism[1–5]. This study was undertaken to assess whether preoperative ultrasound is cost effective.

Patients and methods

The series consisted of 40 consecutive patients who underwent neck exploration for biochemically proved primary hyperparathyroidism at Oulu University Central Hospital. The first 20 patients operated on in 1978–81 did not undergo preoperative ultrasound examination, whereas the subsequent 20 treated in 1982–5 were subjected prospectively to preoperative ultrasound for localization of the enlarged parathyroid glands. The mean (s.d.) preoperative serum calcium concentration was 3·15 (0·22) mmol/l in the former group and 3·23 (0·24) mmol/l in the latter.

All the scans were performed by the same radiologist (H.M.)[6]. The scans were evaluated and reported before surgical exploration. All patients underwent neck exploration by the same surgeon (M.I.K.) in an attempt to visualize at least four parathyroid glands. Frozen section preparations from removed or biopsied parathyroid glands were examined at the time of operation during both series. The choice of operation was the decision of the surgeon. The operative findings were then compared with the preoperative ultrasound assessment by one of the team (E.S.-Z.) using the decision matrix described by McNeil and Adelstein[7]. All the patients were followed up until 31 December 1987.

Results

A solitary cervical adenoma was found in 16 and hyperplasia in four of the 20 patients in each group. In 18 of the 20 patients (90 per cent), the enlarged parathyroid gland was accurately located in tems of site and side whereas, in three studies, ultrasound incorrectly predicted the presence of an enlarged gland where none was found at operation (*Table 1*).

None of the patients died. Transient postoperative hypocalcaemia was encountered in four patients in both groups. In one patient operated on without preoperative ultrasound, the hypocalcaemia proved to be permanent. One other patient in the same group had transient one-sided vocal cord palsy. Two instances of persistent hypercalcaemia and one of recurrent hypercalcaemia occurred in patients without preoperative ultrasound. In the patients undergoing preoperative ultrasound, hypercalcaemia continued after operation in one case. Localization of the enlarged parathyroid glands by ultrasound before neck exploration significantly reduced the number of glands removed at operation and cut down the mean operative time by 20 min ($P < 0{\cdot}05$; *Table 2*). The operative time for the 17 patients with a true positive scan averaged 60 min and that for the remaining three patients with a false positive scan averaged 100 min ($P < 0{\cdot}01$).

Our operating room expenses for neck exploration are at present approximately £7 sterling per min and the total costs of ultrasound of the neck are £70. The total cost of preoperative ultrasound and subsequent neck exploration in patients with a true positive and false positive scan was £490 and £770, respectively. Therefore the overall cost for patients with preoperative ultrasound averaged £532 and that for patients without preoperative ultrasound before exploration £616. Preoperative ultrasound saved £86 per patient and an accurate ultrasound localization saved £126 in operation costs. The net saving arising from the use of preoperative ultrasound in the 20 patients was approximately £1700.

Discussion

The possible advantage of preoperative localization of the abnormal parathyroid glands is generally considered marginal[8]. Operative exploration of the neck nevertheless carries with it a risk of recurrent laryngeal nerve injury and hypoparathyroidism. In instances of adenoma, accurate preoperative localization may help to direct and limit the extent of dissection, and thereby reduce these associated risks. The degree of transient postoperative hypocalcaemia is related to the number of glands removed and biopsied[9]. Unilateral parathyroidectomy with preoperative ultrasound localization of an adenoma may reduce the risk of these complications[3,10]. In the present study there was no demonstrable difference in complication rates between the groups.

Ultrasound localization of the enlarged parathyroid glands before the initial neck exploration significantly reduced the number of glands removed, because the side and site of the glands to be removed was known to the surgeon. This was reflected in the operative time, which was 20 min shorter in this group. On the other hand, the results of a study using two consecutive groups is likely to be subject to errors derived from improved operative technique with increasing experience. It is concluded that the cost-effectiveness of preoperative ultrasound has not been proved, although ultrasound may facilitate and possibly shorten the operation in the future[1–2]. If surgery is limited to the removal of one enlarged gland and one ipsilateral normal gland, as suggested[3,5], accurate preoperative localization by ultrasound would perhaps allow unilateral neck exploration and thus reduce the operative time. In the case of multiglandular disease, a unilateral approach could, however, easily lead to missing double adenomas or asymmetrical hyperplasia on the opposite side.

We conclude that ultrasound reduces significantly both the number of glands removed and the mean operative time. The results suggest that ultrasound localization of the enlarged parathyroid gland before initial neck exploration for primary hyperparathyroidism may be cost effective.

Phenol cauterization for ingrowing toenails: a review of five years' experience

D. S. Byrne and D. Caldwell*

*Departments of Surgery and *Chiropody, Stobhill General Hospital, Glasgow, UK*

Correspondence to: Mr D. S. Byrne, Department of Surgery, Gartnavel General Hospital, 1053 Great Western Road, Glasgow G12, UK

Ingrowing toenails are a common problem causing significant morbidity. Treatments used in the past have met with high failure rates, for example: simple avulsion, 64–70 per cent[1,2]; Zadik's procedure, 16–28 per cent[1,2]; surgical wedge resection of the nailbed, 25 per cent[1,3]; gutter treatment, 48 per cent[4]. In recent years phenol cauterization of the nailbed has been used increasingly. Our early experience of this technique showed a recurrence rate of only 3 per cent[5] and we have now completed a retrospective study of all the patients treated in this way at our clinic in the five subsequent years.

Patients and methods

Patients are referred to our clinic from the Accident and Emergency Department and surgical clinics of this hospital or directly by general practitioners, and are treated by a surgical senior house officers or a chiropodist. Our policy is to perform segmental ablation whenever possible, using a modification of Ross's technique[5,6]. 'Ring block' anaesthesia is used: the toe is exsanguinated by elevation and the application of a 2·5-cm width of an Esmarch bandage (Leyland Medical, Preston, UK); and a rubber tourniquet is placed around the base of the toe. A wedge of nail one-quarter of the total width is then resected from the affected edge using Thwaites' nail-nippers (Footman and Company Ltd., Mitcham, UK). After protecting the surrounding skin with petroleum jelly, 88 per cent phenol is applied to the exposed area, particularly to the sulcus and under the eponychium, using a Black's file (Footman and Company Ltd.) and cotton buds. After 3 min, this is neutralized with surgical spirit before applying a tulle gras dressing and releasing the tourniquet. Patients attend their practice nurse 24–48 h later for a change of dressing and return to the clinic 1 week, 1 month and 6 months postoperatively. They are then discharged if satisfactory healing has occurred.

Between January 1982 and December 1986, 1135 phenol ablations were performed on 850 patients attending this clinic. Reply-paid questionnaires were sent to 313 patients who defaulted from follow-up, enquiring about nail regrowth and recurrent symptoms. Of 162 who replied, 50 reported symptoms and were sent return appointments. The non-responders (151) were excluded from the study.

The 699 patients studied underwent 623 segmental ablations and 308 total ablations, 41 nails were treated on both edges, and 175 patients underwent simultaneous bilateral treatment. Nail spurs growing after previous surgical treatment were avulsed in nine cases and the residual nailbed cauterized. The sex ratio was 367 (male):332 (female) and the age range was 5–88 years (mean 24·9 years). Mean follow-up was 13 months (range 6–60 months).

Results

Sixty-five procedures (6·9 per cent) were deemed failures because of nail regrowth or recurrence of symptoms at the same site. Twenty-eight (43 per cent) of these were in patients who had defaulted from the clinic before 6 months. Twenty-four patients underwent second operations, and no failures were recorded after a minimum follow-up of 7 months (*Table 1*).

The recurrence rate after segmental ablation (4·5 per cent, $n=28$) was significantly better than that after total ablation (11·4 per cent, $n=35$; $P<0{\cdot}05$, testing for the difference between two proportions). All the failed total ablations showed regrowth of nail, which must result from inadequate destruction of the matrix owing to faulty technique or the phenol solution used. Nail regrowth was only apparent in 16 of the failed segmental ablations. The remainder, we believe, were due to insufficient width of nail being excised, resulting in recurrence of symptoms. This is supported by the observation that when both edges of the nail were treated and the width of nail consequently substantially reduced, failures (6 per cent, $n=5$) were all due to nail regrowth. The failure rate following ablation of both edges of a single nail (three of 41 toes, 7 per cent) compared favourably with that after total ablation (11·4 per cent) but this difference did not achieve statistical significance. Two patients undergoing removal of nail spurs had nail regrowth, and both were retreated successfully. Twelve patients had mistaken hyperkeratosis for nail regrowth after total ablations and were educated in the prevention of this condition.

Discussion

Although the first line of treatment of ingrowing toenails remains conservative, surgery is indicated for patients with persisting problems. Our study confirms the very low recurrence rate after phenol ablation observed by Ramsay and Caldwell[5] and reported in other smaller series[7–10]. The results following segmental ablation are particularly good but could be further improved by attention to some points of technique:

1. A sufficient width of nail must be removed. We recommend a full quarter
2. Care must be taken not to leave nail spicules in the sulcus or under the eponychium
3. The phenol must be applied particularly to the nailbed in these two sites and for sufficient time. Previous studies[7] have shown increased failure rates after application of phenol for less than 3 min
4. Absolute haemostasis is essential as blood partly neutralizes the cauterizing effect of phenol[11].

Total ablation of the nailbed has been recommended as the treatment of choice for all ingrowing toenails[7] and specifically for nails affected on both edges[8]. Our results show that segmental ablation produces significantly better results than total ablation, and, although no significant difference between the results after treating both edges of one nail and after total ablation was observed, the preservation of at least part of the nail with the avoidance of hyperkeratosis are significant advantages to the patient. We recommend segmental ablation whenever possible.

Repeated failure has frequently been noted after surgical treatment of ingrowing toenails (e.g. 43 per cent after three avulsions, 34·5 per cent after a second Zadik's procedure[1]), and authors have even suggested that very aggressive techniques such as Syme's terminal amputation be employed after initial failure to avoid such high recurrence rates[12]. We observed no recurrences among the few patients who required a second operation (*Table 1*), and therefore these treatments are considered inappropriate and outdated.

Table 1 *Distribution and results of the ablative procedures used*

	First procedure		Second procedure	
Operation	*n*	Failures	*n*	Failures
Segmental ablation	623	28 (4·5)	7	0
Total ablation	308	35 (11·4)	11	0
Removal of spurs	9	2 (22)	6*	0

Figures in parentheses are percentages. * Four patients who had initially undergone total ablation of the nailbed subsequently underwent removal of regrowing nail spurs

0007-1323/89/060598–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Of the documented failures in this study, 79 per cent occurred within 6 months of operation and this, together with previous observations that almost all failures occur within this period[12], support our postoperative review policy. This study confirms that segmental phenol ablation for ingrowing toenails produces excellent results and it is recommended as the treatment of choice for this condition.

Clinical results of colectomy for severe constipation

K. Yoshioka and
M. R. B. Keighley

Department of Surgery, The General Hospital, Birmingham, UK
Correspondence to:
Professor M R. B. Keighley,
Department of Surgery, 4th Floor
West, Queen Elizabeth Hospital,
Edgbaston, Birmingham B15 2PH,
UK

Subtotal colectomy has been performed in 40 patients with severe constipation. Only one patient was male. Five patients (13 per cent) had a history of a serious psychiatric disorder. Twenty-six patients (65 per cent) could not expel a 100-ml air-filled balloon and 19 patients (48 per cent) had electromyographic evidence of abnormal puborectalis contraction during attempted defaecation before operation. Median preoperative passage of 50 radio-opaque markers over 5 days was 16 per cent. Sixteen patients had had a previous anorectal myectomy to exclude Hirschsprung's disease. Initial resections were subtotal colectomy and ileorectal anastomosis ($n = 34$)*, caecorectal* ($n = 5$) *or ileosigmoid* ($n = 1$) *anastomosis. Secondary operations included restorative proctocolectomy and ileal pouch–anal anastomosis* ($n = 6$) *and six patients eventually had an ileostomy. Median bowel frequency per week significantly increased after operation (0·3 (range 0–1) preoperatively to 21 (range 2–70) postoperatively,* $P < 0{\cdot}005$*), the percentage of patients with abdominal pain fell after operation from 93 to 39 per cent but symptoms of abdominal distension remained the same (86 per cent preoperatively and 82 per cent postoperatively).*

Keywords: Colectomy, constipation, anorectal myectomy, bowel frequency

In the early part of this century, Sir William Arbuthnot Lane (1909) advocated subtotal colectomy and ileorectal anastomosis for the treatment of a variety of disorders, including a condition referred to as chronic intestinal stasis[1]. The operation then fell into disrepute. Colectomy carries a morbidity risk and functional results may be disappointing, hence surgeons are understandably reluctant to remove a colon with no demonstrable structural abnormality[2]. More recently both colectomy with caecorectal anastomosis and colectomy with ileorectal anastomosis have been shown to achieve good results in slow transit constipation[3–6]. There is, however, an incidence of psychiatric disturbance in these patients and although subtotal colectomy often controls the constipation, abdominal pain and distension may persist.

We reviewed the clinical results of subtotal colectomy for severe constipation performed over the last 10 years.

Patients and methods

Colectomy has been performed in 40 patients with severe constipation between 1977 and 1987 One patient was a man and 39 were women. The median age was 35 years (range 19–72 years).

Anal manometry, assessment of rectal sensation and electromyography of the puborectalis were performed in all patients before operation. Colonic transit was studied in all except three patients but colonic motility was evaluated in only 16. The median clinical follow-up was 3 years (range from 5 months to 10 years). A questionnaire was sent to some patients who no longer lived locally to obtain a complete follow-up.

Physiological studies

Anal canal pressures were measured in the left lateral position after rectal examination using a closed water-filled balloon probe attached to a transducer and pen recorder as previously described[7,8] Measurement of resting and squeeze anal pressures were performed at 1-cm intervals 1–5 cm from the anal verge The maximum squeeze pressure was the highest pressure recorded after repeated voluntary contractions at each recording site With a soft latex balloon positioned in the rectal ampulla just above the levator ani, the response of the resting anal pressure to distension with incremental 50-ml aliquots of air to a volume of 400 ml was monitored. A reduction of more than 10 per cent of the resting pressure was recorded as an intact rectoanal inhibitory reflex.

Rectal sensation was assessed using the same rectal balloon. Three parameters of sensation were recorded according to the criteria of Farthing and Lennard-Jones[9] threshold volume, volume associated with constant rectal sensation and volume below 400 ml at which pain became intolerable (maximum tolerable volume). In many of the constipated patients 400 ml caused no apparent discomfort, but a further increase in volume was not attempted for fear of bursting the balloon

The patients were asked to expel a balloon filled with 100 ml of air to evaluate rectal evacuation. During the last 4 years all patients ($n = 27$) have been evaluated by videoproctography in which 100 ml (120 g) of a suspension of Barritop® (Concept Pharmaceuticals, UK) and cellulose is introduced into the rectal ampulla and the anal canal marked with radio-opaque paste. The perineal skin and symphysis pubis are marked using a harness to assess degrees of perineal pelvic floor descent. The anorectal angles are measured at rest, during pelvic floor contraction and during defaecation from frozen frames using a lateral X-ray screening technique that allows measurement of the long axes of the anus and rectum, the latter being determined by calculation of the centroid from a computer program. The degree of rectal evacuation is measured by collection (weight) of contrast material passed in 1 min Any morphological abnormality such as gross perineal descent or rectal intussusception was noted and such patients were excluded from treatment by subtotal colectomy.

Electromyography of the pelvic floor was recorded using a concentric needle electrode at rest and during pelvic floor contraction and attempted defaecation.

Colonic transit was assessed while the patient was eating a normal diet and taking no laxatives. Fifty radio-opaque pellets were taken by mouth and a plain X-ray of the abdomen was obtained 5 days later. Transit was recorded as the percentage of radio-opaque markers passed in 5 days

Sigmoid motility was assessed in 16 patients using a double-lumen catheter placed with its openings at 15 and 20 cm from the anal verge during sigmoidoscopy. The catheter was taped into position and the recording tubes were perfused with saline using an infusion pump at a rate of 2 ml/min Pressures were recorded at both sites at rest for 30 min, followed by a further 30 min after colonic stimulation using 5 mg intrarectal bisacodyl

Operative procedures

All patients underwent subtotal colectomy, 34 had an ileorectal anastomosis, five had a caecorectal and one had an ileosigmoid anastomosis.

0007-1323/89/060600-05$3.00 © 1989 Butterworth & Co (Publishers) Ltd

Earlier surgical procedures

If there was any evidence of rectal dilatation on barium enema, if the rectoanal inhibitory reflex was absent or if there was impaired rectal emptying, patients underwent an anorectal myectomy as already described, both as a potential therapeutic measure and to exclude short segment Hirschsprung's disease[10]. For these reasons 16 patients underwent a preliminary anorectal myectomy; none experienced any long-term benefit from this operation and, because of objective evidence of colonic stasis, the patients later underwent subtotal colectomy. If the rectoanal inhibitory reflex was absent but rectal evacuation was normal, patients had a series of full-thickness rectal biopsies to exclude Hirschsprung's disease; this practice was undertaken in seven of these patients. Before our practice of using anorectal myectomy for outlet obstruction, partial pelvic floor division was used; one such patient in this series had this operation before subtotal colectomy.

Selection of patients

During the period of observation 131 patients underwent some form of operative intervention for chronic long-standing constipation (*Table 1*). Anorectal myectomy was used in 84 patients, although ten of these patients had had an earlier biopsy to exclude Hirschsprung's disease Rectal biopsies had been used in 26 patients, partial puborectalis division in six, rectopexy for secondary rectal prolapse in patients with underlying constipation in 20 and partial subtotal colectomy as a primary procedure in only 15 patients.

Subtotal colectomy was used in 22 patients with slow transit constipation and rectal inertia and in 18 patients having colonic inertia alone. We preferred to offer subtotal colectomy only to those individuals in whom rectal evacuation was normal but there were many patients who continued to require repeated enemas or large doses of laxatives in the group with anismus and colonic stasis in whom colectomy was eventually undertaken.

Results

All patients were shown to have idiopathic slow transit constipation according to the results of our physiological assessment. In addition, megacolon or megarectum was demonstrated on barium enema examination in eight patients, two patients had histological evidence of Hirschsprung's disease and one patient developed severe constipation after rectopexy for full-thickness rectal prolapse. The median history of constipation in the 40 patients having subtotal colectomy was 20 years (range 1–60 years).

Five patients had been previously admitted for psychiatric disorders; three had a history of anorexia nervosa and two had had severe depression.

Twelve patients (30 per cent) have now required further operations after colectomy (*Table 2*). Six patients have had an ileostomy; two of these patients have also undergone a rectal excision. One of these patients had Hirschsprung's disease and could not defaecate even after ileorectal anastomosis and required an ileostomy. She eventually requested a proctectomy and a permanent stoma. The other patient had persistent defaecatory problems and rectal pain after subtotal colectomy and ileorectal anastomosis and eventually requested an end ileostomy and rectal excision. One patient whom we suspect is a chronic abuser of laxatives had such severe diarrhoea after ileorectal anastomosis that she requested an ileostomy. The other three patients were unable to defaecate despite patent ileorectal anastomosis; there was no evidence of megarectum, but none could evacuate material from the rectal ampulla on videoproctography and they all have now elected to have a loop ileostomy.

Six patients have developed a megarectum and impaired rectal sensation with recurrent severe constipation after subtotal colectomy and ileorectal anastomosis and three of the patients were also shown to have rectal inertia on videoproctography. All of these patients have had a restorative proctocolectomy and ileal pouch–anal anastomosis. Three have a duplicated J pouch while the remaining three have a four-lumen W pouch All six patients with pouch–anal anastomosis have complete control of defaecation, and bowel frequency ranges from two to eight times in 24 h but three still complain of abdominal distension and pain. Two of the six patients with pouches originally had a caecorectal anastomosis; the caecum became dilated and they underwent caecal excision and ileorectal anastomosis before further constipation supervened from megarectum.

Results of the preoperative physiological studies are shown in *Table 3*. Anal sensation did not differ from that in a previous group of age- and sex-matched controls Rectal sensation was normal in all except the eight patients with a megarectum. The rectoanal inhibitory reflex was absent in 14 patients (35 per cent), two of whom were shown to have Hirschsprung's disease. Twenty-six patients (65 per cent) were unable to pass a balloon containing 100 ml of air and 19 (48 per cent) exhibited electromyographic evidence of increased electrical activity of the

Colonic motility no response to bisacodyl ($n = 16$)	9 (56%)

*Median and range

puborectalis muscle during attempted defaecation. Seventeen of the 27 patients having videoproctography passed less than 10 per cent of the rectal instillate in 1 min (63 per cent). Colonic transit studies showed that only six patients (15 per cent) passed more than 60 per cent of markers in 5 days and it was thought that all of the patients had taken laxatives after swallowing the pellets. Colonic motility was studied in 16 patients and in nine (56 per cent) there was no response to the administration of bisacodyl. Overall 55 per cent of patients were found to have both outlet obstruction and an inert colon.

Bowel frequency was compared before and after subtotal colectomy in 28 patients (*Figure 1*). Preoperative median bowel frequency was 0·3 times per week (range 0–1 times per week) whereas it was 21 times per week (range 2–70 times per week) after operation ($P < 0.005$). Twelve patients were not assessed because they had had an additional operation. The incidence of abdominal distension and pain was compared before and after operation in those patients with a functioning ileorectal or caecorectal anastomosis (*Table 4*). Twenty-six of these patients (93 per cent) complained of abdominal pain before operation but this persisted in only 11 patients (39 per cent) after operation ($P < 0.02$). Improvement in pain was significantly more common in patients who had had an anorectal myectomy before colectomy because of associated rectal inertia than in those who had not ($P < 0.05$). Abdominal distension was a feature in almost all patients before colectomy and almost invariably persisted.

Twenty-six patients developed complications after operation. Severe diarrhoea was recorded in 13 patients, three of whom had severe perianal excoriation. One of these patients had so much trouble that an ileostomy was raised and one patient with some evidence of perineal descent became incontinent. Fortunately she improved after a later postanal repair. Four patients developed small bowel obstruction and one of these required laparotomy and eventually an ileostomy. Pelvic sepsis was observed in three patients and followed a contained leak from the anastomosis in two. Only one patient had to be returned to theatre to take down the anastomosis; intestinal continuity has now been restored Wound infection occurred in three patients, all of whom had also had pelvic sepsis. Troublesome and repeated small bowel obstruction was recorded in four patients, but only one required surgical intervention.

Some histological abnormality was observed in 22 patients. Melanosis coli was seen in five and an inflamed mucosa thought to be due to laxative abuse was seen in four. Special silver stains revealed some evidence of neuronal degeneration in all 13 colons examined in this way In three cases the appearances suggested a congenital abnormality and the remainder were thought to be acquired possibly from prolonged laxative use.

Discussion

Surgical management options for chronic constipation have ranged from intra-abdominal sympathectomy[11], through vary-

Without previous anorectal myectomy ($n = 16$)	14	13	n s
With previous anorectal myectomy ($n = 12$)	10	10	n s

*Calculated using χ^2 one sample test; n s , not significant ing degrees of partial colectomy[12], to anorectal myectomy, but none of these procedures had proved to be completely reliable for slow transit constipation. Although improvement of bowel frequency and avoidance of laxatives and enemas have been reported following subtotal colectomy[2,4], results are unpredictable and some patients develop diarrhoea Furthermore, abdominal pain and distension may persist. Even when the bowel has been divided at the pelvic brim, the rectum sometimes dilates, resulting in recurrent constipation[13] Caecorectal anastomosis is sometimes associated with dilation of the caecum and recurrent constipation[14]; on the other hand the ileocaecal valve is preserved which might prevent bacterial overgrowth in the small bowel and attacks of pseudo-obstruction. Despite this theoretical consideration, we have now performed 14 further subtotal colectomies for slow transit constipation, there being an equal number of caecorectal and ileorectal anastomoses. No difference in the early functional results has been observed, small bowel transit assessed by breath hydrogen was similar in both groups and the incidence of abdominal distension was the same.

In this series, subtotal colectomy and ileorectal anastomosis was carried out in 34 patients. Subtotal colectomy and caecorectal anastomosis was performed in only five patients but two of these presented within 2 years with persistent constipation due to caecal dilation, one of whom developed a caecal volvulus. Both required conversion to an ileorectal anastomosis but both later developed a megarectum and have eventually had a restorative proctocolectomy. In view of these observations we see no merit in preserving the ileocaecal valve or the caecum and now prefer an ileorectal anastomosis.

The incidence of complications was high in our series. Thirteen patients developed severe incapacitating diarrhoea necessitating an ileostomy in one. Hughes *et al* [15] reported that 41 per cent of patients having partial or total colectomy for constipation subsequently required operation for acute small bowel obstruction due to adhesions. We experienced only four cases of small bowel obstruction after operation and only one required laparotomy. However, this patient required an ileostomy as she could not defaecate despite a patent ileorectal anastomosis even when the small bowel obstruction had been attended to.

The six patients who eventually underwent restorative proctocolectomy and pouch–anal anastomosis are very interesting. They all had a megacolon initially but the diameter of the rectum was judged to be normal. Over a variable number of years the rectum enlarged and became inert. Before restorative proctocolectomy all had solid faeces in the rectal ampulla despite the subtotal colectomy and all had gross impairment of rectal sensation. A balloon inflated with 400 ml of air caused no discomfort and was not even felt by three patients. All have obtained considerable benefit following pouch–anal anastomosis, bowel frequency ranging from two to eight times a day. None experienced soiling or incontinence, none takes antidiarrhoeal agents but three still complain of abdominal distension. All of these patients have been studied after operation The median maximum tolerated volume of the pouch was 350 ml and varied from 250 to 400 ml but all have normal proximal small bowel motility, and reflex contraction of the pouch was observed after distension with 200–300 ml of air. Median percentage pouch emptying was 55 per cent (range 30–75 per cent) It appears therefore that a large entirely inert rectum lacking sensory awareness to distension has been converted to a smaller reservoir which is capable of contraction after threshold distension volume.

Since 1984 we have routinely performed anorectal myectomy on patients with impaired rectal emptying and an absent rectoanal inhibitory reflex in order to exclude Hirschsprung's disease in an attempt to treat outlet obstruction We found that 62 per cent of patients with constipation were improved by anorectal myectomy[10]. Patients with outlet obstruction alone have a much better response to anorectal myectomy than those with evidence of anismus and colonic stasis[16]. Sixteen patients previously treated by anorectal myectomy required colectomy because of persistent constipation; all were improved after the operation and none developed incontinence. In patients with evidence of outlet obstruction and colonic inertia the combination of anorectal myectomy and colectomy might be followed by superior results. Certainly patients having this combination had significantly less abdominal pain than those having subtotal colectomy alone and rectal evacuation was improved. On the other hand it is sometimes difficult to interpret evidence of marker stasis in the colon if constipation is principally due to impaired rectal evacuation.

Preoperative physiological studies showed that 65 per cent of patients could not pass a balloon containing 100 ml of air, 48 per cent had electromyographic evidence of increased electrical activity in the puborectalis during defaecation and 43 per cent had impaired rectal evacuation on videoproctography. Hence over half of these patients (22 of 40) had evidence of rectal inertia as well as colonic stasis. Although 84 per cent of patients had delayed transit of markers only nine of 16 patients (56 per cent) did not respond to bisacodyl infusion The marker test is unreliable if patients take laxatives after their ingestion and a few of our patients found that they could not discontinue laxatives for 7 days because it made them feel ill to do so. However, these physiological studies were unable to predict patients who developed postoperative diarrhoea, or persistent constipation, abdominal pain and distension

The clinical role of these physiological tests needs to be evaluated. We believe that there should be objective evidence of colonic stasis or impaired rectal emptying before embarking on surgical procedures that may be attended by long-term morbidity. Measurement of colonic transit with radio-opaque markers is a crude way of assessing colonic inertia; markers will certainly be retained in the rectum if there is outlet obstruction, hence only markers retained above the pelvic brim should be counted. It is essential that laxatives are withheld for 5 days before and during the period between ingestion and X-ray. Since some patients tend to exaggerate the degree of disturbance, objective proof of colonic stasis is important and may have to be repeated. We have discontinued the use of sigmoid manometry to assess colonic inertia since positioning of the catheters may be difficult and time consuming; furthermore, administration of bisacodyl is sometimes painful. Diagnosis of outlet obstruction is important since we believe that anorectal myectomy is the treatment of choice, videoproctography is now our preferred investigation and electromyography and balloon evacuation are probably unnecessary. As anorectal myectomy is the most reliable way of identifying Hirschsprung's disease and as histopathological evidence of aganglionosis does not correlate with an absent rectoanal inhibitory reflex, anal manometry seems largely superfluous We now believe that selection of patients for the operation can be reliably performed by repeated colonic transit marker studies and videoproctography.

As a result of this experience, we believe that surgical therapy for constipation should only be considered for psychologically stable patients with an identifiable physiological abnormality. If symptoms are intractable and there is evidence of colonic stasis we would now advise a subtotal colectomy and ileorectal anastomosis. If there is outlet obstruction with or without colonic inertia, anorectal myectomy would be advised both for diagnostic and therapeutic purposes. However, patients with both abnormalities must be warned that a subtotal colectomy may be needed if there is no response to anorectal myectomy alone.

Overall only 23 of 40 patients are satisfied with their operation and even then many complain of abdominal pain, bloating or diarrhoea. Twelve patients have required further surgical treatment. Six now have an ileostomy and the other six have required restorative proctocolectomy because of impaired rectal sensation and evacuation. There are few reports of restorative proctocolectomy for functional bowel disease, but the results in six patients who would otherwise have faced a permanent ileostomy are encouraging. We believe that secondary megarectum is an indication for this operation as all our patients are continent and are able to defaecate; however, three of six still complain of abdominal pain and distension.

It is disappointing that the physiological results are unable to predict those patients having a poor outcome. In view of the emotional disorders seen in some of these patients we have embarked upon the use of an assessment of anxiety and depression as a screening procedure before surgical treatment. Preliminary results[17] seem to indicate that patients with high anxiety and depression scores are likely to do badly whatever physiological abnormalities are observed.

Quicker intraoperative colonic irrigation

S. P. Y. Kwok, J. S. Varma and A. K. C. Li

Department of Surgery, Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, New Territories, Hong Kong
Correspondence to. Professor A K. C. Li

Safe primary anastomosis of the colon is now feasible in an emergency operation for left-sided colonic obstruction with the advent of intraoperative irrigation and its refinements[1,2]. Although the technique is gaining acceptance, it can prolong operative and anaesthetic time by as much as 1 h (Reference 2). We have attempted to reduce this extra time by using larger bore delivery tubing and report here our early results.

Technique

Irrigation is performed through a 26Fr Foley urinary catheter inserted via an appendicostomy, with the effluent being collected via a large bore anaesthetic scavenging tube[2]. Normal saline solution is delivered by gravity at a pressure head of 1 m via a glycine giving set (GGS, internal diameter 5 mm) similar to that used for transurethral resection of the prostate. Intermittent antegrade manual massage of the colon, especially of the hepatic and splenic flexures, is performed to facilitate flow. Irrigation is continued until a clear return is obtained.

The results were compared with those achieved by using the conventional blood giving delivery set (BGS, internal diameter 3·5 mm).

Results

Bench-testing of the system revealed that, with a pressure head of 1 m, 4 litres of normal saline solution could be delivered in 10 min via the GGS and in 20 min via the BGS.

At operation ($n=8$), it takes 30–60 min (mean 43, s.e.m. 3·6 min) using the BGS to deliver 4–8 litres of saline solution necessary for irrigation. With the GGS we observed a noticeable reduction in the time taken to obtain clear effluent. In six patients 3–5 litres of saline solution were necessary over a period of 15–30 min for adequate cleansing (mean 24, s.e.m. 2·2 min).

Discussion

Multiple factors determine the rate of flow and hence the time to cleansing of the colon by antegrade irrigation. Many of these are unalterable in the emergency situation, e.g. the length and degree of dilatation of the colon and nature and amount of faecal material present. We have attempted to expedite irrigation by increasing the diameter of the input tubing because the rate of flow through a uniform tube is proportional to the fourth power of its radius (Poiseuille formula). This simple change has resulted in a useful reduction in operative time. It may be possible to reduce the cleansing time further by increasing the input pressures.

Ischaemic strictures in patients treated with a low anterior resection and perioperative radiotherapy for rectal carcinoma

L. Påhlman*,

Dr L. Påhlman

In five (6 per cent) of 78 consecutive patients treated with an anterior resection for rectal carcinoma, a stenosis of the sigmoid colon just above the anastomosis was observed. Four patients had received preoperative radiotherapy over a period of 1 week to a total dose of 25·5 Gy and one patient had received postoperative radiotherapy (60 Gy) over a total of 8 weeks. The length of the stenosis varied from 4 to 120 cm. Two patients subsequently underwent reoperation with an abdominoperineal resection and three patients with a Hartmann procedure. In all patients the inferior mesenteric artery had been ligated close to the aorta. It is proposed that the stenosis may have been due to insufficient circulation in the marginal artery. This insufficiency may have been aggravated by the irradiation, as the retained part of the sigmoid colon was partly included in the irradiation target.

Keywords: Rectal carcinoma, ischaemia, irradiation, anterior resection

Anterior resection is an established surgical procedure in patients with carcinoma of the rectum and rectosigmoid[1–3]. However, in a large group of patients with rectal carcinoma, surgery alone is not sufficient and additional therapy, particularly radiotherapy, has been used. With preoperative or postoperative radiotherapy delivered to a sufficiently high dose, the local recurrence rate has decreased significantly, although there has not been any major impact on survival[4–6]. After preoperative irradiation, a low anterior resection can safely be performed, with no immediate irradiation-related complications[5,7]. However, observations after prolonged follow-up are still sparse. We present five cases of postoperative supra-anastomotic stenosis of the bowel, of different lengths, following low anterior resection. Four patients received preoperative irradiation and one received postoperative irradiation.

Patients and methods

Between October 1978 and December 1985, 122 patients underwent a curative resection for rectal carcinoma at the Department of Surgery of the University Hospital, Uppsala, Sweden. Forty-four patients were treated with an abdominoperineal resection and 78 patients with an anterior resection. In five (6 per cent) of those treated with an anterior resection, stenosis of the sigmoid colon developed above the anastomosis.

From October 1978 until October 1980, all patients with a primarily resectable tumour received preoperative radiotherapy over a period of 1 week to a total dose of 25·5 Gy[6] From October 1980 until December 1985, all patients were randomly allocated to receive either preoperative or postoperative irradiation[7] Preoperatively the dose was 25·5 Gy in 1 week, and postoperatively it was 60 Gy over 7–8 weeks with a 1–2 week interval after 40 Gy. In patients with a tumour higher than 10 cm above the anal verge, the target volume included the posterior part of the pelvic cavity from 5 cm above the anal orifice and the lower lumbar region around the aorta up to the middle of the fourth lumbar vertebra, except for the last 10 Gy of the postoperative radiation when the upper limit was below the sacral promontory. If the tumour was situated below the 10-cm level, the anal canal was also included in the target

The patients were followed up every third month during the first 2 years, twice a year up to 5 years, and then once a year. No patient has been lost to follow-up.

Case 1

A 54-year-old man with insulin-treated diabetes mellitus underwent an anterior resection in October 1981 after preoperative radiotherapy. The tumour (Dukes' C) was situated 12 cm from the anal verge The postoperative course was uneventful, but the patient had severe problems with frequent bowel movements. An X-ray examination of the colon 25 months postoperatively revealed a 4-cm stricture of the bowel just above the anastomosis. Repeated endoscopic biopsies showed no cancer but slight non-specific inflammation and submucosal fibrosis. Computed tomography over the region disclosed no signs of recurrent tumour. A sigmoidostomy was performed but the rectum was left.

Case 2

A 69-year-old previously healthy man underwent an anterior resection in June 1983 after preoperative radiotherapy The rectal tumour (Dukes' A) was situated 12 cm from the anal verge There were no postoperative complications Twenty-six months later, investigation of diarrhoea showed a supra-anastomotic stricture 4 cm long. The patient underwent an emergency Hartmann procedure. Multiple biopsies from the stenotic site showed oedema, slight fibrosis and a non-specific inflammatory reaction.

Case 3

A 63-year-old previously healthy woman with a tumour (Dukes' A) situated 6 cm from the anal verge underwent a low anterior resection after preoperative irradiation. Postoperatively an abscess developed in the rectovaginal septum, but no anastomotic leakage was found. The patient also had repeated problems with urgency postoperatively. Twenty-six months later an acute obstruction occurred and a barium enema revealed a 20-cm stenosis of the sigmoid colon just above the anastomosis (*Figure 1*). The patient underwent reoperation with an abdominoperineal resection. Macroscopically the bowel was extensively thickened and firm and histopathological examination showed extensive fibrosis in all layers with no signs of recurrent tumour.

Case 4

A 64-year-old woman was admitted in May 1985 with a rectal tumour (Dukes' B) situated 10 cm from the anal verge. After preoperative irradiation, a low anterior resection was performed. The postoperative course was uneventful. Twelve months postoperatively the patient became constipated and an X-ray examination revealed a 15-cm supra-anastomotic stricture. Reoperation was carried out with the intention of performing an abdominoperineal resection, but a huge liver metastasis was found and only a sigmoidostomy was performed. Sections from the thickened part of the sigmoid colon showed oedema and fibrosis but no cancer.

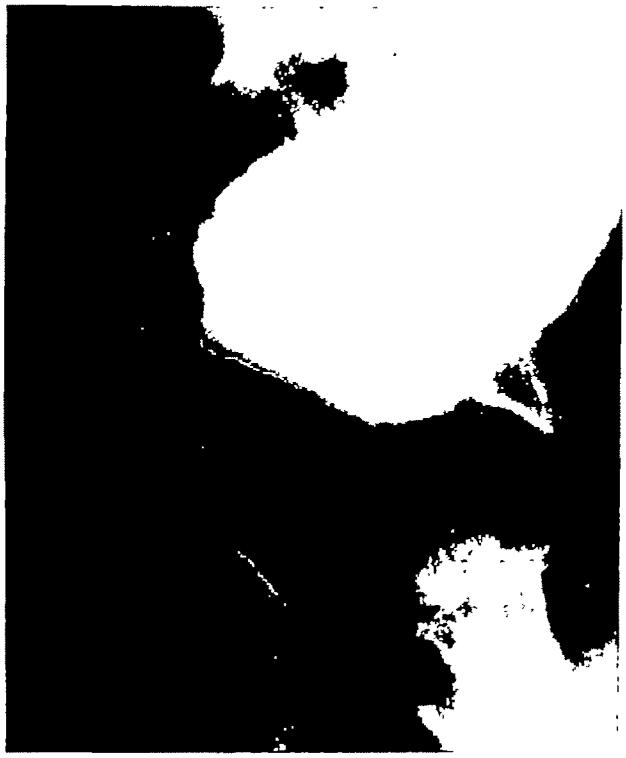

Figure 1 *Barium enema radiograph of a 63-year-old woman with an obstruction showing a 20-cm preanastomotic stenosis of the sigmoid colon*

Case 5

A 40-year-old previously healthy man with a rectal tumour (Dukes' C) situated 11 cm from the anal verge underwent an anterior resection in March 1983. As the patient was allocated to the postoperative irradiation group he subsequently received 60 Gy. The postoperative period was uneventful. In August 1985, a transverse loop colostomy was performed because of colonic ileus On X-ray examination a 7-cm supra-anastomotic stenosis was found, and 1 month later an abdominoperineal resection was undertaken. On histopathological examination no recurrent tumour was observed, but the bowel wall was extremely thick and microscopy showed fibrosis in all layers

Discussion

Anastomotic stricture is a well-known phenomenon in patients treated with an anterior resection. However, these strictures are short (0 5 cm) and (most likely) due to anastomotic leakage. Such a stricture is easy to treat with balloon dilatation. In the five cases described here, the strictures were considerably longer and there was no real suspicion of anastomotic dehiscence except in case 4. To our knowledge, there are no reports in the literature of such long stenoses following an anterior resection As all these patients received additional irradiation, and because this is a fairly new treatment in patients with rectal carcinoma, it is important to determine whether or not the stenosis described in the sigmoid colon is partly or entirely attributable to the irradiation.

The irradiation was given with a three-field technique with the patient in a prone position[8]. This technique allowed delivery of a high dose to the tumour area with relative sparing of the surrounding normal tissues. Only the distal part of the sigmoid colon was included within the target and thus received the prescribed tumour dose The proximal part of the sigmoid colon received a considerably lower dose. The part of sigmoid colon included in the 'full-dose' target was resected in the four cases where the irradiation was delivered preoperatively However, in the patient who received postoperative irradiation, the strictured part of the colon was placed within the target. Except in this latter case it is therefore unlikely that the stenosis is a direct effect of the irradiation on the affected segment of the colon. The dose was also below that usually considered necessary to cause fibrosis of the colon

Histopathological examinations of repeated biopsies from all cases and from the resected bowel in two cases showed variable fibrosis in most layers, sometimes in addition to oedema and/or non-specific chronic inflammation. There were no detectable changes indicating any specific aetiology

It is also unlikely that the strictures were due to any infectious complication, as all but one patient had an uneventful postoperative recovery. On the other hand, all patients underwent a high-tie resection, i.e. with ligation of the inferior mesenteric artery at the aorta. With such a resection the blood flow to the sigmoid colon is dependent on a well-functioning marginal artery.

It is possible that this complication is due to insufficient circulation in the marginal artery. It is also conceivable that the effect of this insufficiency may have been aggravated by the concomitant irradiation. It should be mentioned that the doses used, both preoperatively (25·5 Gy in 1 week corresponds to a dose of 46 Gy in 4–5 weeks if given in 2 0 Gy fractions) and postoperatively (60 Gy in about 8 weeks) were higher than in most reported studies, which may explain why this phenomenon has not been reported earlier[4,9–11]. On the other hand, according to experimental data, the minimal dose required to kill micrometastases with a high degree of probability is about 45 Gy given over 4–5 weeks, or a comparable dose with other fractionation schedules[12] Nevertheless, before any firm conclusions can be drawn, further reports on this complication and its relation to irradiation have to be evaluated. Whatever the mechanism, the contribution of irradiation must be explored.

Sixteen subjects (mean (s.d.) age 50·7 (12·8) years, three men) were studied on two separate occasions by two experienced investigators in random order. A standard protocol of anatomical, manometric and electrophysiological assessments of anorectal motor and sensory function was followed. No significant differences were found between the results obtained by the two investigators in the measurements of perineal descent, anal canal length, anal canal resting pressure and squeeze pressure, pudendal nerve terminal motor latency, single-fibre electromyography fibre density of the external anal sphincter, and thresholds of mucosal electrosensitivity. This study shows that the standard tests of anorectal sensorimotor function are repeatable by different investigators. In addition, it suggests that comparison of data obtained in different centres using these techniques is valid.

Keywords: Anorectal physiology, repeatability

Anatomical, motor and sensory tests of anorectal function have been used extensively for research into abnormalities of pelvic floor function, in particular the investigation of the pathogenesis of idiopathic faecal incontinence[1–8]. The information obtained from these tests in normal subjects has increased the understanding of the mechanism of continence, and of the pathogenesis of other forms of pelvic floor dysfunction, such as the solitary rectal ulcer syndrome[9–11] and the obstructive defaecation of young constipated women[12–15]. The tests have also been used to assess objectively the results of postanal repair[16,17] and as an adjunct to clinical assessment in the management of patients with anorectal disorders. Despite the increasing use of these techniques there has been no objective assessment of the interobserver repeatability. The aim of this study was to measure the repeatability of the standard tests of anorectal motor and sensory function.

Patients and methods

Sixteen subjects (mean (s.d.) age 50·7 (12·8) years, three men) were studied on two separate occasions by two experienced investigators (J.R. and S L) in random order. The mean delay between the two tests was 20 days (range 14–39 days). The clinical diagnosis in each subject is shown in *Table 1*. The subjects were studied in the left lateral position.

Anatomical position

The perineal position was measured in centimetres at rest and on straining to defaecate using a perineometer[18] This device measures the position of the perineum in reference to the plane of the ischial tuberosities The amount of descent was calculated by subtraction of the strain value from the rest value.

Tests of motor function

Anal manometry, functional anal canal length, and resting and maximum squeeze pressures. These were measured using a closed water-filled system consisting of a 4-mm diameter microballoon mounted on a polyethylene tube 2 mm in diameter connected to a pressure transducer (Statham Instruments Incorporated, Hato Rey, Puerto Rico) and a pen recorder (Devices®, Lectromed Ltd., Jersey, UK). The system was calibrated in centimetres of water at ambient temperature and pressure. The balloon was lubricated with K-Y jelly (Johnson and Johnson Ltd., Slough, UK) and gently inserted into the rectum, the pressure was continuously monitored as the balloon was removed in 1-cm stations. This allowed the maximum resting pressure and functional length of the anal canal to be recorded. The balloon was reinserted into the anal canal to record the maximum voluntary squeeze pressure In addition, the midanal canal resting and voluntary contraction pressures were measured.

Pudendal nerve terminal motor latency (PNTML). This was measured using a specially constructed finger-stall[4], with stimulating electrodes mounted at the tip and recording electrodes mounted at the base connected to a standard electromyographic recording machine (Neuromatic 2000-M, Dantec Ltd., Bristol, UK). The stimulator was inserted into the rectum and a supramaximal stimulus (8 3 ma, 0·1 ms) delivered to the pudendal nerve on each side. The action potential of the external anal sphincter was recorded by the base electrodes of the stimulator, allowing measurement of the latency of conduction[2].

Single fibre electromyography (EMG). Using a sterilized fine needle electrode with a recording surface of 25 μm diameter (Dantec, 13K87, Dantec Ltd.) recordings of up to 20 different single muscle fibre electrical potentials were made. Analysis of the tracings by agreed criteria allowed the calculation of the fibre density[2,19], an index of motor unit clustering – a consequence of denervation and subsequent reinnervation

Tests of sensory function

Mucosal electrosensitivity (MES)[8,20] This was measured using a specially constructed probe comprising two platinum electrodes placed 1 cm apart near the tip of a 10 Fr polyvinyl catheter graduated in centimetres. Copper wires connected the electrodes to a constant current generator (Department of Medical Physics, BESA, Bristol, UK), supplying 0 1-ms square wave stimuli at a constant rate of 5 pulses

per second The probe was lubricated with K-Y jelly and inserted to the midpoints of the upper, middle and lower thirds of the anal canal which were determined by measurement of the functional anal canal length. The current across the electrodes was increased in steps of 0·1 ma until a threshold of sensation was reported by the patient, usually as a burning or tingling sensation. Three measurements of the threshold were made at each site and the lowest reading was recorded For the assessment of repeatability the functional anal canal length measured by the first operator was used to divide the anal canal into thirds for the second test of electrosensitivity, preventing bias due to a possible difference in assessment of functional length.

Statistics

Statistical analysis of the data for repeatability is taken from Bland and Altman[21]. The bias is the mean difference between the two methods for the measurement of the variable. The 95 per cent confidence intervals show the precision of the estimate.

Results

The results are summarized in *Table 2*.

Anatomical position

There was good agreement between the two studies for the measurement of perineal position at rest (*Figure 1*) and on straining and the degree of descent calculated from these measurements (*Table 2*).

Motor function

Manometry. The agreement between the two studies for the measurement of resting (*Figure 2*) and voluntary contraction pressures showed insignificant bias of −9 and −10 cmH_2O, respectively The 95 per cent confidence intervals, however, were large from −25 to 4·7 cmH_2O for resting pressure and from −32 to 14 cmH_2O for voluntary contraction pressure. Agreement for midpoint anal canal pressure showed a bias of −7 cmH_2O (95 gper cent confidence interval from −16·3 to 2·3) at rest and 1·5 cmH_2O (from −26·1 to 29·1) on voluntary contraction.

Electromyography. The bias for the electromyographic tests of PNTML (*Figure 3*) and calculation of fibre density (*Figure 4*) were very small and agreement was excellent. Repeatability for the calculation of fibre density derived from single muscle fibre EMG studies was assessed by arranging for each investigator to analyse the other's coded tracings, so that the identity and diagnosis was unknown. Agreement was excellent: bias −0·003, 95 per cent confidence interval from −0·07 to 0·06.

Sensory function

Agreement between the two studies for thresholds to mucosal electrostimulation in the anal canal were excellent with insignificant bias (*Figure 5*).

Discussion

This is the first objective assessment of the repeatability of the standard tests of anorectal sensorimotor function. In this study these standard tests showed a high degree of repeatability when two independent investigators, experienced in the techniques, examined the same subjects on separate occasions.

Manometry, although repeatable in terms of calculated bias, had large 95 per cent confidence intervals. In terms of precision, manometry was the least repeatable of all the tests. Pressure measurement at the midpoint of the anal canal did not improve the degree of agreement. This is an important observation as manometric assessment is the most commonly used test of motor function. The variation may be due to normal day-to-day variation in pressure in the anal canal, to differences in patient compliance or to differences in the technique used by the investigators.

In contrast, single-fibre EMG and PNTML tests were highly repeatable with very narrow limits of agreement and confidence intervals, indicating good precision. This finding supports the use of single-fibre EMG fibre density and PNTML measurements in addition to manometric tests of anorectal motor function.

Mucosal electrosensitivity was highly repeatable which is an interesting finding as the thresholds depend on the response of the subject to a perceived stimulus, in contrast to the tests of motor function which are objective Other tests of sensation in

the anorectum are available such as temperature sensitivity[22] of the anal canal or balloon distension of the rectum[8], but these are either too complicated (temperature), or too unreliable (rectal distension)[8,23] for routine use.

The sensorimotor tests of anorectal physiology used in this study are quick and easy to perform, a full test taking approximately 35 min. The equipment is standardized and readily available. This study shows that the standard tests of anorectal sensorimotor function are repeatable by different investigators. In addition, it suggests that comparison of data obtained in different centres using these techniques is valid.

Management of infection after prosthetic abdominal rectopexy (Wells' procedure)

A. H. McL. Ross and J. P. S. Thomson

St. Mark's Hospital for Diseases of the Rectum and Colon, London, UK
Correspondence to:
Mr A H. McL. Ross, Surgical Unit,
Broomfield Hospital, Broomfield,
Chelmsford, Essex CM1 5ET, UK

The management and results of treatment of eight cases of implant infection after a Wells' rectopexy for rectal prolapse are reported. Most infections presented within 3 months of the rectopexy. Fever, abdominal or pelvic pain, diarrhoea, and the passage of pus per rectum were common presenting features. Removal of the infected implant per rectum or per vaginum was successful in four of five attempts and is the recommended initial approach, particularly in cases occurring early after surgery. Despite removal of the implant early after rectopexy recurrent prolapse did not occur.

Keywords: Rectal prolapse, infection, rectopexy

Since 1959 when Wells described an abdominal rectopexy using a prosthetic implant for the management of full-thickness rectal prolapse it has proved to be a popular and safe method of management[1]. Its efficacy in preventing recurrent prolapse has been proved in a number of published series[2–6]. Furthermore, the operation is relatively simple to perform compared with those previously employed and is well tolerated even in a population that includes many patients who are aged and infirm.

The most serious potential postoperative problem is infection of the synthetic implant. Such an event is unusual but necessitates the removal of the implant and may result in considerable morbidity. Little published evidence exists about the mode of presentation, treatment and long-term consequences of such infection. This paper reports eight such patients who were referred to and treated at St. Mark's Hospital and reviews previous published experience

Patients and methods

Eight patients treated for infected implants after posterior rectopexy are reviewed Three patients had the rectopexy carried out at St. Mark's Hospital, representing all identified implant infections after rectopexy at this hospital The remainder were operated on elsewhere.

Polyvinyl alcohol sponge was implanted in seven of the patients and Mersilene® (Ethicon Ltd., Edinburgh, UK) mesh in one. All three patients treated initially at St. Mark's Hospital received perioperative antibiotic cover, generally gentamicin and metronidazole. Case records and X-rays were examined and each patient was interviewed. Presenting symptoms and signs, treatment and postoperative progress, with particular reference to continence, the presence of anal discharge and any recurrence of prolapse were assessed

Results

A summary of the features of each patient is presented in *Tables 1* and *2*. Follow-up ranged from 3 months to 9 years. Symptoms developed from 1 week to 6 years after operation and had been present for between 10 days and 20 months before treatment. Pelvic pain, fever, and the discharge of pus per vaginum or per rectum were common features at presentation.

On rectal examination, pelvic induration, a palpable mass and tenderness were usual At sigmoidoscopy two patients had visible sinuses entering the rectum (*Figure 1*). A perirectal cavity was demonstrated by contrast enema in three cases (*Figure 2*). In three patients who developed rectal strictures, infection had been present for a prolonged time (6–18 months) before implant removal Two of these patients had diarrhoea and one required rectal excision. The other patient's diarrhoea (No 2) and stricture resolved after removal of the prosthesis although she remains occasionally constipated.

Two cases had developed a ureteric stricture and presented with back pain in one case and urinary frequency in the other. Both were confirmed by intravenous urography. In patient No. 5 the problem settled after removal of the prosthesis. In No 1 ureterolysis was performed successfully.

Five implants were removed per rectum or per vaginum. In general, artery forceps were used to enlarge any sinus present thus allowing removal of the implant *in toto* or piecemeal If no sinus was present a formal posterior proctotomy was made over the inflammatory mass to allow implant removal. In one case the implant was removed using an intersphincteric approach. In one patient (No. 6) the implant was removed per rectum after it proved impossible to remove it at laparotomy when a Hartmann's operation was performed. In patient No 1, piecemeal, incomplete removal only was achieved after three operations and the patient has undergone rectal excision because of persistent sepsis and stricture.

The implant was removed at laparotomy in a further three patients, one of whom (No. 4) developed a postoperative ureterocutaneous fistula treated by nephrectomy.

At the time of writing, three patients have colostomies. The other five patients without colostomies consider themselves continent of solid stool and none has developed recurrent prolapse. One patient (No. 4) continues to complain of low grade non-specific abdominal pain.

Discussion

Transabdominal rectopexy using an implant sponge or mesh is a safe, effective and popular operation for full-thickness rectal prolapse[2–7] Serious complications are uncommon despite the often frail state of patients who undergo the operation. In Wells' original description, polyvinyl alcohol sponge was used and since then polypropylene mesh, polytetrafluoroethylene sheet, and Mersilene mesh have all been used as alternatives. Boulos *et al.*[8] have recently suggested that if patients can be followed for long enough a high rate of prolapse is associated with the use of polyvinyl alcohol sponge[9] rectopexy. Suturing the mobilized rectum directly to the presacral fascia without insertion of an implant, avoids the risk of infection and appears to be effective in controlling prolapse[7,10].

Implant infection is an infrequent complication with an incidence variously reported between 0 and 16 per cent[2–6,11] Infection is either the result of endogenous infection after inadvertent breach of the rectal lumen or exogenous infection The presence of a postoperative pelvic haematoma may encourage such infection. Prosthetic sepsis usually presents early after rectopexy. In this series, six of eight patients developed symptoms within 3 months of operation, although

symptoms had been present for much longer before eventual treatment. Pelvic pain, fever, discharge of pus per rectum or per vaginum and diarrhoea are common features and should alert the clinician to the possibility of implant infection if they occur postoperatively.

On examination there may be a fever, and digital rectal examination reveals perirectal tenderness and induration. Pus may be seen in the lumen of rectum and vagina, and a visible sinus may be present. In this series a contrast enema revealed a perirectal cavity in three patients, although only one had a visible sinus on sigmoidoscopy. A contrast enema should not be required routinely.

Opinion is divided on the optimum method of removal of the infected implant. Of 13 cases reported in the literature, most (ten) have been managed by removal at a further laparotomy, some authors commenting on the ease with which this was achieved. Lake *et al.*[11] have suggested removal at laparotomy particularly in those cases where sepsis is long established. Our results suggest that such a policy may be unnecessary, technically difficult, and hazardous to surrounding viscera. Two of our cases, managed by laparotomy, were complicated by operative damage to adjacent viscera and, in both, sepsis had been present for a considerable time before operation. In contrast, particularly when the septic complication had been present for a short period, removal per rectum or per vaginum was, in general, simple to achieve and atraumatic. Such an approach was adopted with success in three of four cases of infection recorded by Morgan *et al.*[2], two of which occurred within 3 weeks of the initial rectopexy.

Although no trials comparing infection rates using different implant materials exist, it is interesting to note that the use of polypropylene has been associated with no complicating infection[6]. Lack of published detail on the use of prophylactic antibiotics prevents any accurate assessment of their value in preventing implant infection[2,5,11]. Nevertheless, in achieving a zero infection rate after rectopexy using polypropylene mesh, Keighley *et al.*[6] employed a 24-h regimen of wide spectrum antibiotics and it is our practice always to administer such a regimen (aminoglycoside and metronidazole) when an implant has been used.

The absence of recurrent prolapse, even when the implant was removed soon after surgery, confirms others' experience[2,5]. This presumably reflects the effect of perirectal fibrosis induced by infection, and encourages early removal of the implant after the diagnosis of infection has been made. Continence appears to be unaffected by this complication.

Avoidance of contamination and pelvic haematoma by meticulous surgical technique is clearly the priority in management. If infection does occur, the diagnosis should be recognized early. This will often allow transrectal or transvaginal removal of the implant and avoid an unnecessary laparotomy.

Anal canal length, anal canal resting and squeeze pressures, ileal pouch capacity and pouch compliance were measured in 104 patients after ileal pouch–anal anastomosis but before ileostomy closure. The intention was to determine if such parameters were associated with late functional outcome after re-establishment of intestinal continuity. Functional outcome in terms of stool frequency (day and night), incontinence (day and night), perianal pad use, perianal skin irritation, and the use of constipating agents was assessed for all 104 patients 1 year or more (median 438 days) after ileostomy closure. A low mean anal sphincter resting pressure before ileostomy closure was associated with subsequent nocturnal incontinence ($P < 0{\cdot}05$) *and, to a lesser extent, the need to use constipating agents* ($P = 0{\cdot}08$). *Pouch compliance if low before ileostomy closure was associated with an increased frequency of nocturnal stool frequency after 1 year* ($P < 0{\cdot}05$). *Anal canal length, anal sphincter squeeze pressure and pouch capacity before ileostomy closure were not related to subsequent functional outcome in these patients.*

Keywords: Anorectal manometry, ileal pouch–anal anastomosis, functional outcome

Removal of the entire colonic mucosa, and hence its malignant potential, is an established part of the management of patients with chronic ulcerative colitis and familial adenomatous polyposis. Proctocolectomy in these patients has been increasingly followed by anastomosis of an ileal pouch to the anus[1]. Patient satisfaction with this restorative procedure is extremely high[2]. However, a proportion of patients with an ileal pouch–anal anastomosis are persistently troubled by excessive stool frequency and episodes of minor and major incontinence. We wished to determine if there were any factors that could be quantified early, before re-establishment of intestinal continuity, which might be associated with late pouch function. Therefore, we measured anal canal pressures at rest and on squeezing, pouch capacity and pouch compliance in 104 patients with an ileal pouch–anal anastomosis before closure of the ileostomy. Our purpose was to determine whether there was a correlation between the measurements of anal canal and reservoir function and functional status of the patients 1 year or more after ileostomy closure.

Patients and methods

Patients

All patients who had a diverting ileostomy closed after an ileal pouch–anal anastomosis at the Mayo Clinic between January 1984 and June 1986 were considered eligible for this study. This period was chosen to ensure at least 1 year of follow-up for each patient after ileostomy closure. In addition, the manometry technique used during this time was performed in a uniform manner using a perfused probe.

Ileal pouch–anal anastomosis was performed in all patients according to the technique described by Ballantyne *et al*[3]. A short (3–5 cm) rectal muscular cuff was retained in each patient and no patient underwent rectal mucosal excision using the eversion technique

Clinical outcome was recorded for each patient in standard fashion Details ascertained included stool frequency during the day and night, incontinence (day and night), the use of pads, perianal irritation, and the continued use of the constipating agents loperamide and diphenoxylate hydrochloride

Before ileostomy closure, each patient had anal manometry and the pouch volume and compliance were measured A rigid 1·2-cm diameter polyglass probe with four perfused ports oriented 90° apart was used to measure radial pressures in the anal canal The probe was inserted into the ileal pouch transanally and was then withdrawn using a 1-cm station pull-through technique as described by Heppell *et al*[4]. In this way, the length of the canal was determined. Resting pressures at each level were recorded along the length of the anal canal. The procedure was repeated but with the patient squeezing on the probe at each 1-cm interval The highest basal pressure recording in each patient was designated the maximum resting pressure, and averaging the recorded resting pressures gave the mean resting pressure. The maximum and the mean squeeze pressures were derived similarly. For each patient, therefore, five manometric measurements were recorded: anal canal length, mean resting pressure, maximum resting pressure, mean squeeze pressure and maximum squeeze pressure.

On completion of anal manometry, a 12-cm-long flaccid latex rubber balloon attached to a small tube (outside diameter 2·6 mm) was inserted into the ileal pouch. The balloon was then inflated with air in increments of 10 or 20 ml This was continued until the patient complained of pelvic discomfort or a strong urge to evacuate. The volume of air in the balloon at this point was taken as the maximum ileal pouch capacity The pressure in the balloon when maximum ileal pouch capacity was reached was used to calculate pouch compliance in millilitres per millimetre of mercury (e.g 120 ml/60 mmHg = 2·0 ml/mmHg).

Statistical analysis

From the anal manometry and pouch measurements seven variables were determined: anal canal length, mean and maximum resting pressures, mean and maximum squeeze pressures, pouch capacity, and pouch compliance A total of seven factors measured outcome after ileostomy closure: these were stool frequency (day and night), incontinence (day and night), use of pads, perianal irritation, and use

of loperamide and diphenoxylate hydrochloride. Linear regression analysis was used to determine statistically significant associations ($P < 0·05$) between the manometry and pouch measurements and the measurements of clinical outcome.

Results

A total of 307 patients were identified as having had a diverting ileostomy closed after an ileal pouch–anal anastomosis. Of these, 104 (*Table 1*) were referred for measurement of anal canal pressures and pouch capacity and compliance before ileostomy closure as part of a routine preoperative evaluation, which also included pouchography. No patient was referred for evaluation of a perceived problem with the pouch or anal sphincters. The median follow-up period for these patients after ileostomy closure was 438 days (range 319–1101 days)

The 104 patients studied were virtually identical to the 203 patients not studied in terms of age distribution, sex, colonic pathology, type of ileal pouch, and the incidence of postoperative complications. Clinical outcome for the 104 patients studied and the 203 other patients was also similar in terms of stool frequency, incidence of incontinence, and the use of pads and constipating medication. Perianal irritation, however, was more common in the 104 patients studied than in the 203 other patients, but this difference did not reach statistical significance (55 per cent *versus* 36 per cent, $P > 0·05$)

Stool frequency

Daytime. The length of the anal canal and anal canal resting and squeeze pressures were similar in patients with both a high daytime stool frequency (seven or more) than those with a lower daytime stool frequency (six or less). Pouch capacity before ileostomy closure was, if anything, slightly higher in patients who subsequently had the most frequent daytime stool passage Pouch compliance, however, was slightly lower in the latter patients than in those patients with less frequent daytime bowel movements. None of these differences was of statistical significance.

Night-time. Anal canal length was similar in patients with few stools at night (one or less) and in patients with more frequent nocturnal stools (two or more). Anal sphincter pressures and pouch capacity were slightly higher in those patients who passed few stools at night, but these differences were not significant. By contrast, pouch compliance before ileostomy closure was significantly higher in patients with few night-time stools (median 2·3 ml/mmHg) than in those with more frequent nocturnal bowel movements (median 1·8 ml/mmHg, $P < 0·05$; *Figure 1*).

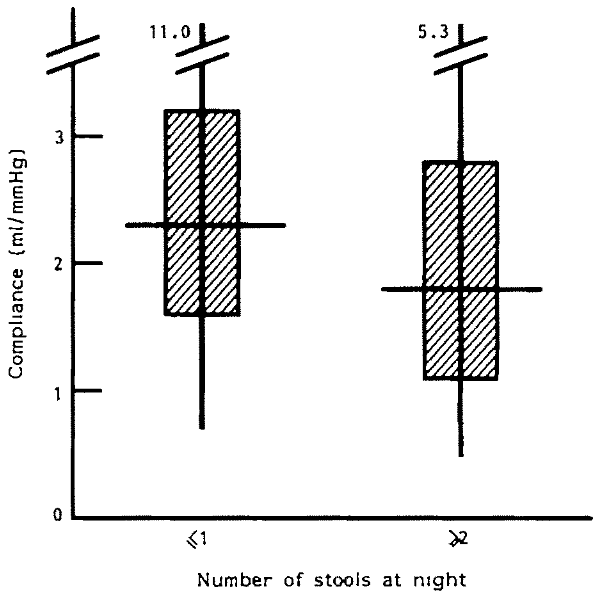

Figure 1 *Pouch compliance (volume/pressure at maximum capacity)* versus *night-time stool frequency. Median, interquartile range and range are shown Patients with one stool or less at night at follow-up had more compliant pouches before closure of the ileostomy than patients with two or more stools at night* ($P < 0·05$)

Incontinence

Daytime. The majority of patients (81 per cent) in this series had perfect daytime continence; only a single patient had frequent daytime incontinence. The length of the anal canal was not related to the frequency of daytime incontinence. Anal sphincter pressures were higher in patients with perfect continence than in patients with occasional incontinence, but not significantly. Pouch capacity before ileostomy closure was marginally greater in patients with subsequent incontinence than in patients with perfect continence, while pouch compliance did not differ between groups.

Night-time. Occasional incontinence at night was more common (40 per cent *versus* 17 per cent) than during the day. Anal sphincter pressures in general tended to be higher in patients who were continent at night; this difference was statistically significant only for the mean resting anal canal pressure ($P < 0·05$, *Figure 2*). Pouch capacity before ileostomy closure was similar in patients who were continent and in those who were incontinent. Pouch compliance did not differ between patients with no incontinence and those with either occasional or frequent nocturnal incontinence.

Pads, perianal irritation and constipating agents

The length of the anal canal was not related to the use of pads, the presence of perianal skin irritation or the use of constipating agents. However, anal canal resting pressures tended to be higher in patients who did not wear pads, did not report perianal skin irritation, and did not require constipating agents. The higher mean resting anal canal pressures seen in patients who did not need constipating medication failed to reach statistical significance ($P = 0·08$; *Figure 3*). Anal sphincter squeeze pressures were similar in patients who did or did not use pads, those with or without perianal skin irritation, and in patients who did or did not take hypomotility agents. Similarly, pouch capacity and pouch compliance before ileostomy closure showed little association with the use of pads, perianal skin irritation and the need for constipating medication.

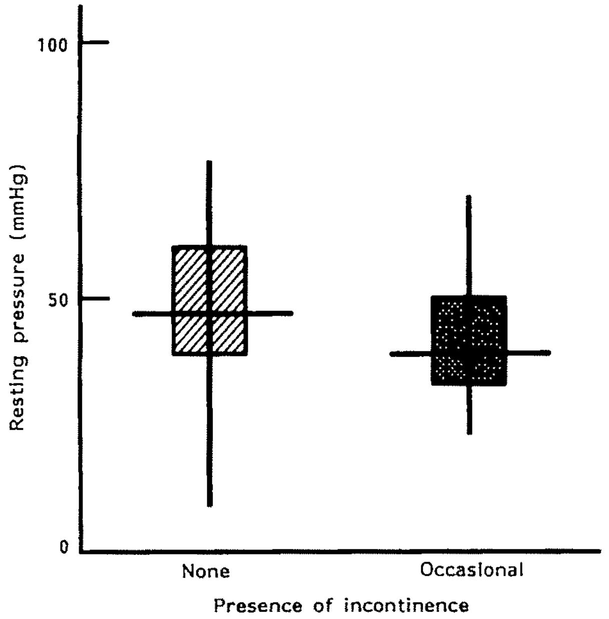

Figure 2 *Anal canal resting pressure* versus *night-time incontinence. Median, interquartile range and range are shown. Patients with no night-time incontinence at follow-up had higher resting pressures before ileostomy closure than patients who had occasional incontinence* ($P < 0{\cdot}05$)

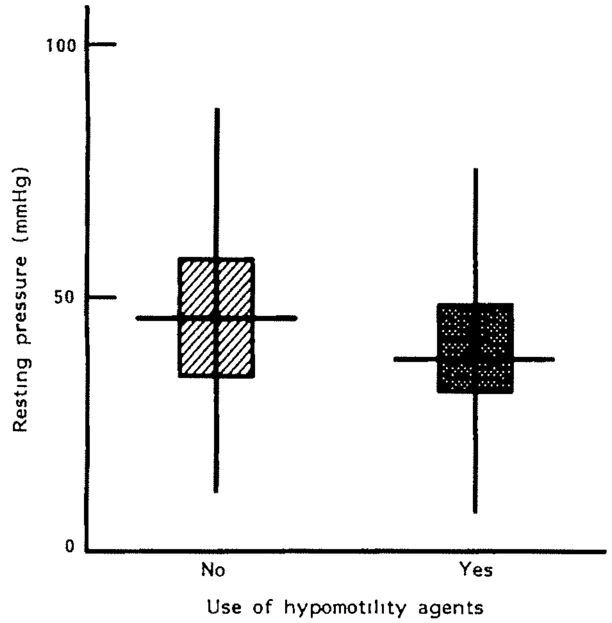

Figure 3 *Anal canal resting pressure* versus *use of hypomotility agents. Median, interquartile range and range are shown. Patients who did not use hypomotility agents at follow-up tended to have higher resting pressures before ileostomy closure than patients who did* ($P = 0{\cdot}08$)

Discussion

Patient dissatisfaction after ileal pouch–anal anastomosis is the result primarily of frequent and/or inappropriate discharge of stool. While the total stool volume presented to the pouch during 24 h is important in determining stool frequency[5], anal canal pressures and properties of the ileal pouch itself are likely to have key roles in determining clinical outcome[6,7]. This study examined these two factors, which were measured before closure of the diverting ileostomy, to determine if they correlated with pouch function 1 year after ileostomy closure.

Anal canal squeeze pressures measured before ileostomy closure in this study were not correlated with incontinence, pad use, perianal skin irritation or the need for constipating medication more than 1 year after ileostomy closure. By contrast, low mean anal sphincter resting pressure was associated with nocturnal incontinence and, to a lesser extent, with the use of constipating agents after ileostomy closure. Others have also described minor faecal leakage after ileoanal anastomosis as being a consequence of reduced resting anal pressures[8]. Resection of the rectal mucosa and/or the associated anal dilatation may be responsible for this diminution in resting anal canal pressures; avoiding this latter type of proctectomy significantly reduces the minor leakage reported by patients after conventional ileal pouch–anal anastomosis[8]. These observations, however, have been disputed recently by Keighley *et al.*[9].

The capacity of the ileal pouch measured after ileostomy closure is clearly related to pouch function assessed at the same time[5,6,10,11]. In contrast, the volume of the unused ileal pouch, as measured in this study and by Becker and Raymond[11], before ileostomy closure does not correlate with late stool frequency. This latter finding would be difficult to explain if, as has been suggested, the intraoperative volume of the double loop ileal reservoir (J pouch) is not significantly different from the volume of the reservoir measured 12 months after ileostomy closure[10]. However, the volume of an ileal J pouch does expand rapidly after ileostomy closure[11]; this explanation would then account for the absence of correlation between pouch volume before ileostomy closure and pouch function 12 or more months after ileostomy closure.

Evidence of an association between compliance of the pouch after ileostomy closure and daily stool frequency is, at best, equivocal. While one study reported an inverse correlation between frequency of defaecation and pouch compliance[6], others have failed to find the same relationship between pouch compliance and pouch function[5]. In contrast, a finding in this study was that night-time stool frequency more than 1 year after ileostomy closure was associated with pouch compliance measured before ileostomy closure. This result is similar to that reported previously for 22 patients with an ileoanal anastomosis followed for 1 month after ileostomy closure[4].

The apparent association between preclosure pouch compliance and subsequent stool frequency and the irrelevance of preclosure pouch capacity to the same outcome is of interest. Much ingenuity has been devoted to developing a pouch which achieves a large intraoperative volume[10]. However, if it is pouch compliance that is important to stool frequency after an ileal pouch–anal anastomosis, and not capacity[12], this latter approach may be a faulty one, that is, investigators should be more concerned with improving pouch compliance and not merely capacity. Whether or not pouch 'compliance' is a fixed property of the ileal wall or is amenable to changes in pouch design[6] requires further study.

In summary, we examined the relationship between measurements of anorectal manometry, pouch capacity and compliance obtained before ileostomy closure and the clinical outcome 1 year later for 104 patients with an ileal pouch–anal anastomosis. Anal canal length, anal squeeze pressures and pouch capacity before ileostomy closure were not related to late functional outcome in these patients In contrast, low anal sphincter resting pressures postoperatively were associated with nocturnal incontinence, while low pouch compliance was associated with increased nocturnal stool frequency. The results of this exploratory analysis suggest, firstly, that further prospective studies controlling for confounding variables are warranted and, secondly, that modifications of surgical technique which minimize stretch of and trauma to the anal sphincter apparatus and increase pouch compliance also require further investigation.

Technique of laparoscopic appendicectomy

P. F. Leahy

Department of Surgery, Hant's Regional Hospital,
Windsor, Nova Scotia, Canada
Correspondence to: Dr P F. Leahy, Box 2320,
Windsor, Nova Scotia, BON 2TO, Canada

Recently laparoscopic surgery has found numerous therapeutic indications. Its many advantages over laparotomy have prompted its use by gynaecologists. This article presents a technique for appendicectomy using operative pelviscopy.

Patients and methods

Four patients with appendicitis were offered laparoscopic appendicectomy. The procedure was explained to the patients who agreed to have surgery performed by the laparoscopic technique

The procedures were performed under general anaesthesia After skin preparation, a Surgineedle® (US Surgical Corporation and Auto Suture, Connecticut, USA) was introduced in an infraumbilical position and CO_2 was insufflated slowly using a CO_2 insufflator (Karl Storz, Culver City, California, USA) A trocar and laparoscope were inserted through the infraumbilical wound and the clinical diagnosis was confirmed Using transabdominal illumination by the laparoscopic light source, the inferior epigastric vessels were identified and avoided when inserting a 5-mm trocar through a separate incision, and a second trocar, 11 mm in size, was inserted above the anterior superior iliac spine Through the respective trocar a grasping forceps and Filshie clip (Karl Storz) applicator were inserted The appendicular artery and the base of the appendix were each ligated with Filshie clips After division of the appendix it was extracted through the trocar without contamination of the wounds If the wounds required closure they were closed with 3 × 0 plain catgut Marcain® (Winthrop, Aurora, Ontario, Canada) 0·5 per cent was infiltrated as a matter of routine The patients were generally fit for discharge the following day. There were no complications in this series and the patients returned to work or normal activities within 1 week

Discussion

Laparoscopic appendicectomy can be performed with minimal morbidity[1]. In the hands of skilled laparoscopic surgeons the procedure can be performed within 10 min and when combined with regional anaesthesia can allow the very early discharge of the ambulatory patient. The presence of an acute appendix in a retrocaecal position makes the procedure a more difficult operation. The training of surgeons in this technique poses obvious difficulties, as very few general surgeons have expertise in operative pelviscopy. The advantages of laparoscopic appendicectomy over laparotomy are numerous. With thermocoagulation, haemostasis is achieved easily Using bipolar coagulation the risk of thermal injury to the surrounding organs is reduced The absence of postoperative adhesions is important especially in female patients.

This technique is relatively simple, fast and safe in the hands of experienced laparoscopic surgeons and could set a precedent for modern ambulatory surgery.

External and internal anal sphincter responses to rectal distension in normal subjects and in patients with idiopathic faecal incontinence

J. J. Bannister*, N. W. Read, T. C. Donnelly and W. M. Sun

**Department of Surgery and Sub-department of Human Gastrointestinal Physiology and Nutrition, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF, UK*

Correspondence to:
Professor N. W. Read

The responses of the external anal sphincter and the internal anal sphincter to rectal distension were studied in 18 female patients who had idiopathic faecal incontinence with perineal descent and 11 female control subjects, by measuring pressures at six sites within the anal canal and the electrical activity of the external sphincter. The pressure profile in the normal anal canal, at rest, was asymmetric with the highest pressure recorded in the outermost channels. Rectal distension caused a transient increase in the activity of the external sphincter, which was associated with an increase in anal pressure, particularly in the outermost two channels. This was followed by a symmetrical reduction in anal pressure throughout the anal canal, caused by relaxation of the internal sphincter and shortening of the high-pressure zone. Two patterns of response were observed in the patients with idiopathic incontinence. Twelve patients (group 1) showed normal anal relaxation, but the maximum anal pressures recorded during rectal distension or a conscious squeeze were abnormally low, suggesting weakness of the external anal sphincter. The remaining six subjects (group 2), who were older than the group 1 patients, had much lower resting pressures and showed only external sphincter contraction in response to rectal distension, with no obvious internal sphincter relaxation. However, the maximum pressures recorded during a conscious contraction of the external sphincter were lower in this group than in the normal control subjects. These results suggest that group 2 patients have impaired internal anal sphincter tone, as well as external anal sphincter weakness. This may explain why all except one of the group 2 patients, compared with only 17 per cent of group 1 patients, reported incontinence to both solids and liquids.

Keywords: Faecal incontinence, anus

Incontinence to faeces is prevented by the resistance of the anus to the passage of rectal contents. This is made up of two components, the smooth muscle of the internal anal sphincter and the striated muscle of the external anal sphincter. Distension of the rectum relaxes the internal sphincter[1] with a concomitant reduction in anal canal pressure. This response has been called the rectoanal inhibitory reflex and appears to be mediated by the enteric nerves. Anal relaxation, in response to rectal distension, is often associated with a compensatory contraction of the external sphincter. This contractile response has been called the 'inflation reflex'[2] and, while it may be a true spinal reflex, it is heavily modulated by conscious mechanisms[3].

It is technically difficult to separate the components of the anal sphincter mechanism, because the smooth muscle of the internal sphincter and the voluntary muscle of the external sphincter have a large degree of anatomical and functional overlap. Schuster *et al.*[4] attempted to record from the two muscles, by siting two balloons in the anal canal: the inner balloon recording predominantly from the internal sphincter, and the outer balloon recording from the bulk of the external sphincter. This technique affords only a partial separation of the actions of the voluntary and involuntary muscles of the anal sphincter.

We have developed a combined multiport manometric and electromyographic technique, which allows us to separate and identify the individual actions of the internal and external sphincters. In this study, the technique has been used to describe the action of the two muscles during rectal distension in normal volunteers and to characterize the abnormalities found in patients with idiopathic faecal incontinence.

Patients and methods

Subjects

The normal group consisted of 11 women (five nulliparous, three multiparous, i.e. more than three children) who were aged between 20 and 51 years (median 36 years) and were either healthy hospital workers or patients admitted for treatment of surgical conditions not involving the gastrointestinal tract. The incontinent patients were 18 women (one nulliparous, eight multiparous) aged between 28 and 75 years (median 59 years). Episodes of incontinence occurred at least once a day in 11 patients and between once a day and once a month in the remainder. Seven patients were incontinent to both solids and liquids, the rest were only incontinent when their motions were liquid. Clinical examination revealed no evidence of generalized neuropathy or myopathy or previous sphincter trauma, though all of the patients had abnormal descent of the pelvic floor (more than 2 cm) on straining.

Methods

Pressures were measured at six sites in the anal canal, during serial inflation of a rectal balloon with increasing volumes of air[5]. The probe was a polyvinyl seven-lumen tube, external diameter 5 mm (Mui, Missisauga, Ontario, Canada). Six of the channels terminated in side holes situated 0·5, 1·0, 1·5, 2·0, 2·5 and 3·5 cm from the anal margin and were perfused with water, at a rate of 1 ml/min, using a low compliance

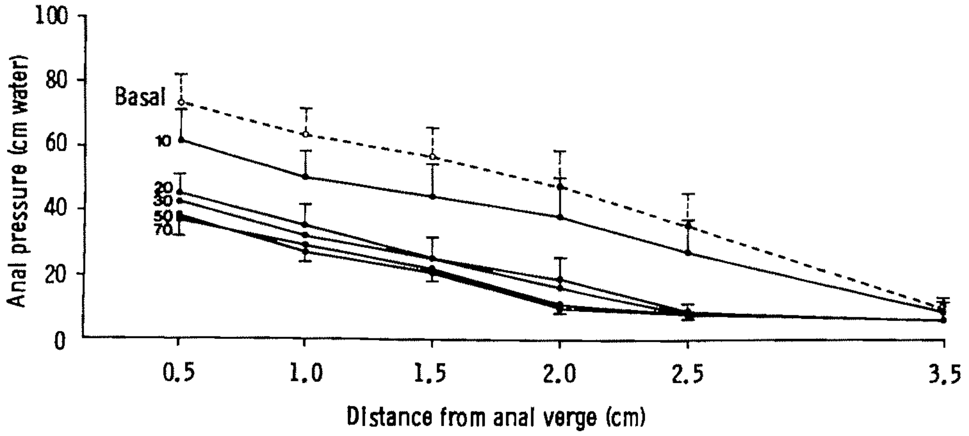

Figure 1 *The anal pressure profile at rest and during distension of a rectal balloon with 10, 20, 30, 50 and 70 ml of air. Results are the means (s e m) of data from 11 control subjects*

reservoir and capillary tubing (Mui) Intraluminal pressure was measured by means of water-filled transducers (Statham 230B, Oxnard, California, USA) situated in each infusion line, and the output of each transducer was recorded on an eight-channel recorder (Hewlett Packard 7758A, Waltham, Massachusetts, USA) The seventh channel terminated in a small latex balloon, manufactured from the teat of a rubber condom (LRC Products Ltd, London), located so that its lower pole was 7 0 cm from the anal margin

The electrical activity of the external sphincter was assessed in six control subjects and 15 incontinent patients by means of a bipolar electrode, consisting of two Trimel (Johnson Mathey Metals Ltd , Southgate, London, UK) coated wires (diameter 0 025 mm) with the ends bared, hooked and offset to avoid electrical contact[6] The wires were inserted into the superficial part of the sphincter[7] using a fine gauge hypodermic needle, which was subsequently withdrawn, leaving the hooked wires *in situ*. The free ends of the wires were bared and attached to an amplifier (Type 14A 11 electromyograph, DISA, Copenhagen, Denmark), which was connected via an integrator to the chart recorder.

With the subject lying in the left lateral position, the probe was positioned in the anorectum using a proctoscope, and the electomyograph wires were inserted into the external sphincter Both the probe and the wires were taped to the buttocks to prevent movement during the test Fifteen minutes were allowed for the anal canal to adapt to the presence of the tube The rectum was distended by inflating the terminal balloon with 10 ml of air Distension was maintained for 60 s. The balloon was then deflated and, after a recovery period of at least 60 s, it was reinflated at a rate of approximately 20 ml/s, with the previous volume plus 10 ml This procedure was continued to a balloon volume of 100 ml.

In addition, maximum basal and maximum squeeze anal pressures were measured, in all patients and controls, by the station pull-through technique[8]

Statistical analysis

Statistical analysis was performed using the Student's *t* test and Wilcoxon's rank sum test for parametric and non-parametric data respectively.

Results

Normal subjects

The resting pressures in the anal canal described an asymmetric profile with the greatest pressures recorded caudally (*Figure 1*). The maximum resting pressure was defined as the highest pressure recorded at any point in the anal canal, after the pressure had stabilized to steady levels.

Distension of the rectum caused an initial increase in anal pressure, most obvious in the more caudad channels and accompanied by an increase in the electrical activity of the external sphincter (*Figure 2*). The maximum contractile response was defined as the maximum increase in pressure induced, at any site in the anal canal, at any volume of rectal distension. This response was followed by a reduction in pressure, throughout the anal canal, to values that were below the resting levels (*Figure 2*) The reduction in anal pressure was not associated with any decrease in the electrical activity of the external sphincter. In most cases the sphincter activity remained elevated above the resting levels throughout the period of distension (*Figure 2*). The depth of relaxation increased with distending volumes up to 50 ml and the highest pressure recorded in any of the anal channels during anal relaxation, induced by rectal distension with volumes exceeding 50 ml, was termed the maximum residual pressure If we can assume that the internal sphincter was maximally inhibited by volumes of 50 ml and above, the maximum residual pressure reflected the residual activity of the external sphincter.

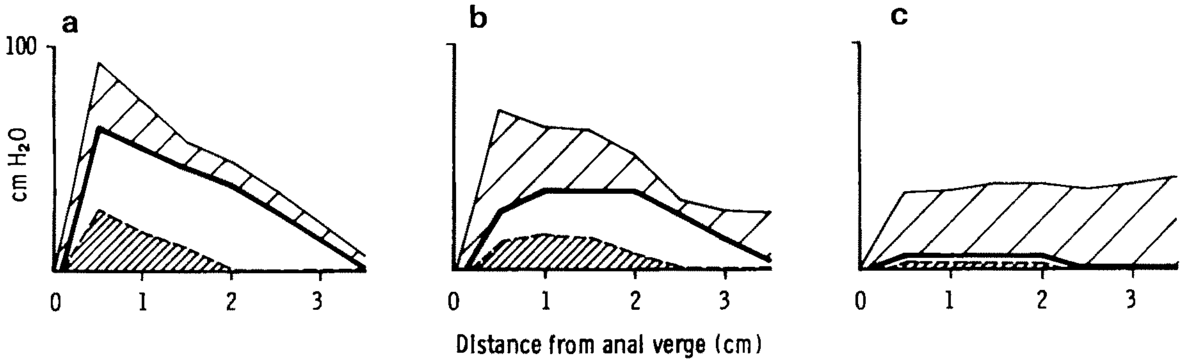

Figure 3 *Average profiles of resting pressure (———), residual pressure (----) and maximum pressure recorded during the inflation reflex (—) in* **a** *normal subjects,* **b** *group 1 incontinent patients with normal anal relaxation and* **c** *group 2 incontinent patients with no anal relaxation*

The depth of relaxation observed with each rectal volume was virtually identical at each recording site up to 2·0 cm from the anal margin (*Figure 1*). The innermost recording site, situated 3·5 cm from the anal margin, was almost certainly in the rectum, as the pressures in this channel were always very low and no relaxation was observed on rectal distension. If that is correct, the ports, situated 2·5 and 2·0 cm from the anal verge, recorded rectal pressure when the rectum was distended with volumes of 20 or 50 ml, respectively (*Figure 1*). Thus, because of the asymmetry of the anal pressure profile, lower volumes were required to produce a maximum inhibition of the inner anal ports than of the outer anal ports, and the sphincter appeared to shorten as the rectum was distended (*Figure 1*).

At small distending volumes, the sphincter showed only transient relaxations, the pressure returning to basal values whilst the balloon was still inflated. As the distending volume increased, the sphincter tone remained below the resting levels for the duration of the distension, but rose rapidly to levels that often exceeded the resting pressures when the balloon was deflated (*Figure 2*). This 'rebound' rise in pressure was usually, but not invariably, accompanied by a transient increase in the electrical activity of the sphincter (*Figure 2*), which was always shorter.

Incontinent subjects

The incontinent patients showed two patterns of anal response to rectal distension. Twelve patients (group 1) aged 28–75 years (median 49 years) showed normal anal relaxation, but the contractile responses were absent in two cases and maximum resting pressures, maximum pressures recorded during the 'inflation reflex' and maximum residual pressures were all lower than in the controls (*Table 1, Figure 3*). The pressure profiles differed from the control subjects in that the maximum resting and residual pressures were recorded between 1 and 2 cm from the anal margin and not in the outermost channels (*Figure 3*). The maximum reduction in anal pressures recorded during rectal distension was not significantly different from that observed in the normal controls (*Table 1*) although, unlike normal subjects, the relaxation was asymmetrical, being maximal in the inner channels.

The remaining six patients (group 2), aged 52–75 years (median 65 years), showed no anal relaxation in response to rectal distension (*Figure 4*). The maximum resting pressures in these patients were lower than in the control group and group 1 patients ($P<0{\cdot}05$; *Table 1, Figure 3*). The contractile responses to rectal distension were similar in amplitude to those of the normal controls (*Table 1*), although the maximum anal pressures, recorded during a contractile response, were lower than in the normal group or group 1 incontinent patients ($P<0{\cdot}05$; *Table 1, Figure 3*). The steady-state pressures recorded during rectal distension (corresponding to the residual pressure in the other groups) were lower than in the controls (*Table 1*).

During station pull-through, the maximum basal and the maximum squeeze pressures were significantly lower in both groups of incontinent patients compared with control subjects, and the maximal basal pressures in group 2 incontinent patients were lower than those in group 1 patients (*Table 1*).

Patients in group 2 tended to suffer more severe symptoms than those in group 1; five out of six patients in group 2 but only two out of twelve patients in group 1 ($P<0{\cdot}05$; Fisher's exact test) were incontinent of solids as well as liquids

Discussion

The results show that the normal anal sphincter is asymmetric; the resting pressure is not uniform along its length, but is higher caudally. The asymmetry can be explained by the tonic contraction of the external sphincter, the bulk of which is situated around the outer anal canal. The initial brief increase in pressure, induced by rectal distension, is associated with an

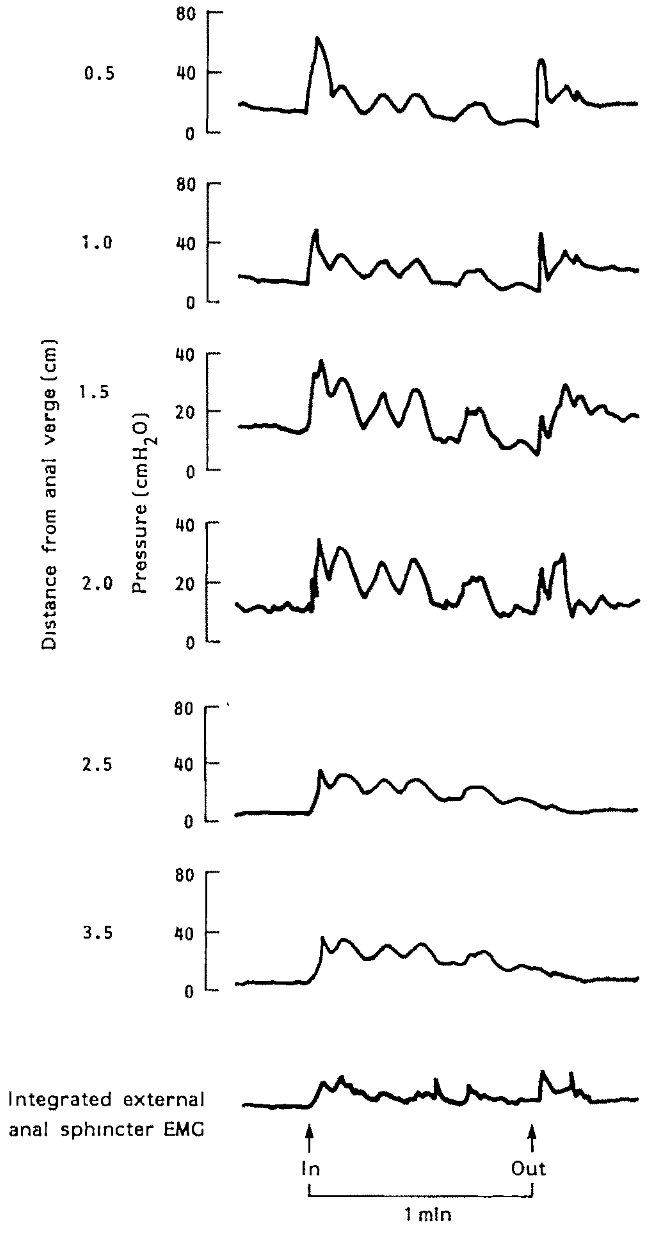

Figure 4 *Multiport recording of anorectal pressure and the electrical activity of the external anal sphincter in a patient with idiopathic faecal incontinence (group 2) during inflation of a rectal balloon with 50 ml of air. In, inflation, out, deflation, EMG, electromyograph*

increase in sphincter electrical activity and accentuates the anal pressure gradient. The ensuing reduction in anal pressure, which is caused by relaxation of the internal sphincter, induces a similar degree of relaxation in pressure throughout the anal canal, indicating that the sphincter is functionally homogeneous along the length of the anal canal in normal subjects

Increasing the volume of distension up to 50 ml increases the depth and the duration of relaxation. This causes the pressure in the upper anal canal, 2·0 and 2·5 cm from the anal margin, to fall to values that are equal to those recorded in the innermost port (3·5 cm from the anal margin), which is assumed to be situated in the rectum Thus, the anal sphincter shortens during rectal distension due to relaxation of the internal sphincter, while the concomitant contraction of the external sphincter maintains continence by keeping the outer anal canal tightly closed. The impression, gained from these manometric studies, corresponds to the radiological appearances during distension of the rectum with barium[9]. Thus, as has been previously suggested, relaxation of the internal sphincter could allow the rectal contents to be sampled by receptors in the upper anal canal[10], while continence is preserved by contraction of the external sphincter.

Comparison of the residual with the resting pressures suggests that the external sphincter could provide up to 50 per cent of the resting tone of the sphincter in normal subjects. This value is considerably higher than previously published data[11,12], and may be explained by the fact that rectal distension can cause a prolonged stimulation of external sphincter activity (*Figure 2*), and therefore residual pressure probably provides an overestimate of resting tone.

It is often assumed that the puborectalis contracts at the same time as the external sphincter but, if this is so, it does not increase the pressure in the inner anal canal. This is hardly surprising, as contraction of a muscle that loops around the posterior aspect of the inner anal canal will move the inner anus forward and accentuate the anorectal angle, but will not increase the intraluminal pressure unless movement of the upper anus is prevented by a relatively fixed object such as the prostate gland in the male or perhaps the cervix uteri in the female.

Deflation of the rectal balloon is often accompanied by a brief increase in sphincter pressure, which is related to a correspondingly transient increase in the electrical activity of the external sphincter, and a more sustained increase in sphincter tone, which is presumably caused by increased activity in the internal sphincter, as external sphincter activity rapidly returns to resting levels after balloon deflation

Studies carried out in incontinent patients revealed two distinct manometric patterns in response to balloon distension Most patients (group 1) showed a normal pattern of relaxation. The resting and residual pressure profiles in these patients differed from those in normal subjects in that the maximum pressure was recorded at the midpoint of the anal canal instead of at the caudad pole, suggesting a relative weakness of the external sphincter. This conclusion was supported by the relatively low squeeze pressure, measured by the station pull-through technique, and by the low maximum residual pressures in this group. The maximum decreases in anal pressure, induced by rectal distension, were similar in amplitude in this group to those observed in the control group, implying normal internal sphincter tone, though the asymmetric profile of relaxation may suggest impaired tonic contraction of the internal sphincter in the outermost anal channels.

The remainder of the incontinent patients showed no anal relaxation in response to rectal distension Their very low basal pressures excluded the possibility that they had Hirschsprung's disease[13–15]. Instead, the results suggest that the internal sphincter is abnormally weak and making little, if any, contribution to the anal sphincter pressure. Rectal distension in these patients increased the pressure in the anal canal in a pattern that resembled the profile of the integrated electrical activity of the external sphincter. These observations resemble the pattern, previously observed during continuous rectal infusion of saline, when 59 per cent of a group of patients with severe faecal incontinence showed no anal relaxations, but showed instead regular increases in pressure throughout the anorectum[16]. The external sphincter pressure and electrical responses to rectal distension in group 2 patients were similar in amplitude to the corresponding responses recorded in control subjects, although the maximum squeeze pressure was not only lower than in the normal controls, but also lower than in group 1 patients. The maximum residual pressure, a measure of external sphincter tonic activity, was also lower in group 2 than in controls. Thus, it would appear that in group 2 patients internal, as well as external, sphincter function is impaired This could explain why more group 2 patients were incontinent to solids as well as liquids. The older age of the group 2 patients would be consistent with a progression from a situation dominated by external sphincter weakness into one in which the internal sphincter is also impaired.

Internal sphincter weakness has been suggested to be partially responsible for the faecal incontinence seen in diabetic patients with autonomic neuropathy[17]. None of our patients had diabetes mellitus or any other signs of autonomic nerve dysfunction. However, all of them had external sphincter impairment and abnormal descent of the pelvic floor. Perhaps the internal sphincter normally requires some structural support to maintain normal tone. If so, exposure to traction from the unsupported tissues of the pelvic floor could result in stretching of the sphincter and apparent weakness. Another possible mechanism may involve stretch damage to the arteries or the fragile autonomic nerves that supply the sphincter.

The role of the internal sphincter in the pathophysiology of faecal incontinence is controversial. An abnormally weak sphincter would presumably allow the liquid faeces direct access to the anal canal. This may mean not only that the external sphincter would have insufficient time to respond to the entry of faeces into the rectum but also that it may become densensitized by continuous exposure to rectal contents. Another important factor is that there seems to be a reciprocal relationship between the contractile activities of the external and internal sphincters; when the internal sphincter is relaxed during rectal distension, the external sphincter contracts to maintain continence; when the external sphincter is relaxed during micturition it is the tone in the internal sphincter that preserves continence[18]. Thus, it seems logical that impairment of both muscles should lead to more severe incontinence than impairment of one muscle alone.

The tone of the internal sphincter, unlike the external sphincter, can be influenced by pharmacological agents. Loperamide has been shown to increase resting sphincter pressure and to modulate the internal sphincter response to rectal distension[19]. α-Adrenoreceptor agonists enhance internal sphincter tone *in vitro*[20,21] and *in vivo*[22] and have been used to treat urinary incontinence. The use of such agents in patients with idiopathic incontinence and demonstrable internal sphincter weakness may prove a useful adjunct to alternative modes of treatment.

Paper accepted 5 January 1989

Surgical Research Society

Br. J. Surg. 1989, Vol. 76, June, 622–624

The 69th Meeting of the Surgical Research Society took place on 5 and 6 Janury 1989 at the University of Kent, Canterbury. The Meeting was organized by Professor Williams and the staff of the Department of Surgery at The London Hospital, and Professor G. R. Giles was in the Chair. A Symposium entitled 'Gastrointestinal motility for the surgeon' preceded the free paper sessions. One hundred and four papers were read, and the Patey Prize was awarded to Mr M. G. Dunlop, for his presentation entitled 'Familial adenomatous polyposis (FAP): gene order at the FAP gene locus with evidence to support the hypothesis that the germ line mutation is sufficient for the development of colonic adenomata'. A selection of papers and abstracts is published on pp. 622–649.

Rehabilitation after lower limb amputation: a comparative study of above-knee, through-knee and Gritti–Stokes amputations

A. Houghton, A. Allen, R. Luff and I. McColl

Department of Surgery, Guy's Hospital, London SE1, UK
Correspondence to:
Professor I. McColl

A study of 169 unilateral amputees under three Disablement Services Centres was performed. The study comprised 88 above-knee, 54 through-knee and 27 Gritti–Stokes amputations. Satisfactory rehabilitation occurred in 33 per cent of above-knee, 62 per cent of through-knee and 44 per cent of Gritti–Stokes patients (56 per cent overall). The better rehabilitation of through-knee versus *above-knee amputees* ($P<0\cdot02$) *was also found in a group of patients matched for comparable age and duration of amputation as well as in a group of age-matched vascular amputees. Through-knee amputees relied significantly less on wheelchairs than above-knee* ($P=0\cdot016$) *and Gritti–Stokes* ($P=0\cdot05$) *amputees. The prosthesis used for the through-knee and Gritti–Stokes amputations was considered unsightly in 50 per cent of cases* (versus *31 per cent for the above-knee prosthesis).*

The superior rehabilitation with through-knee amputations should prompt us to improve both our technique for this amputation and the prostheses currently available. A through-knee amputation should be performed in preference to an above-knee amputation in the case where either is surgically possible, and a below-knee amputation not feasible.

Keywords: Amputation, rehabilitation, lower limb

In 1986 there were 5596 new referrals for artificial limbs in England, Wales and Northern Ireland[1] These were mainly for lower limb amputations A below-knee amputation is preferred where possible[2–4], but may fail to heal in up to 30 per cent of cases, resulting in a higher amputation[4–6].

When a more proximal amputation is needed there is controversy over the place of the Gritti–Stokes, through-knee and above-knee amputations. Proponents of the Gritti–Stokes amputation point to the superior primary healing (75–90 per cent of cases), rapid postoperative mobility owing to the long lever, and low perioperative mortality rate of around 10 per cent[7–9]. Like the Gritti–Stokes amputation, the through-knee amputation has a perioperative mortality rate of 10 per cent, but has been suggested to have a lower primary healing rate[3,10]. The broad, strong bulbous stump does, however, provide total end-bearing and there is no need for a pelvic band to prevent rotation. A standard above-knee amputation is associated with a higher perioperative mortality rate of 20 per cent[7,10,11], but has the advantage that the prosthesis is cosmetically superior and weighs less than a comparable through-knee or Gritti–Stokes prosthesis.

There is, however, little in the literature comparing rehabilitation following these three amputations Many surgeons aim to preserve the maximum amount of the patient's own limb on the assumption that any extra limb length must be beneficial. Others have been convinced of the prosthetic advantages of the above-knee stump and have adopted a policy of performing an above-knee amputation whenever a below-knee amputation is not possible[12]

This study was designed to assess patients with these three lower limb amputations, looking specifically at their rehabilitation from the time of first attendence for prosthetic treatment. It was therefore a study of potential limb-wearers and was designed to help answer the question: 'If a below-knee amputation is impossible, which amputation offers the patient the best chance of successful rehabilitation'

Mean number of years after amputation (range)	24 (1–71)	14 (1–64)	9 (1–71)

Patients and methods

The names and addresses of 250 patients with above-knee, through-knee and Gritti–Stokes amputations were obtained from the Disablement Services Centres of Roehampton, Gillingham and Brighton We eliminated from this study bilateral amputees, congenital limb deficiency and amputees under the age of 20, leaving 229 patients The date of amputation and its level was determined from the notes Questionnaires were then sent to each patient. Rehabilitation was assessed by the answers to four questions (*Table 1*) A score of nine or more was accepted as satisfactory rehabilitation The patients were also asked whether they had a wheelchair and for how many of their waking hours they used it. The answers to these questions were analysed to assess the patients' wheelchair dependence.

The reasons for patients not wearing their prosthesis were assessed Was this due to tenderness of the stump, blisters or ulcers, the limb being generally uncomfortable or cosmetically unattractive? In a separate question the patients' views were sought about the cosmesis of the artificial limb Statistical difference between the groups was assessed using the Mann–Whitney U test

Results

Questionnaires were sent to 229 amputees and the response rate was 74 per cent. Useful replies were received from 169 patients (132 male and 37 female). These replies are shown in *Table 2*

There was no difference in the mean age of the different amputation groups. However, above-knee amputees had had their amputation a mean of 24 years previously compared with 14 years for through-knee amputees and 9 years for Gritti–Stokes amputees. Above-knee amputees were therefore younger on average when prosthetic treatment started.

In view of these differences we selected a group of responders for comparable age and duration of amputation. This group included 16 Gritti–Stokes, 21 through-knee and 23 above-knee amputees.

Of the 169 replies, eight patients (4·7 per cent) had no functional use of their limb (*Table 3*)

The cause of the amputation could be determined from the notes in 78 per cent. Trauma was responsible in 48 per cent and vascular disease in 34 per cent Other causes, including bone tumours, polio and developed non-union accounted for the remaining 17 per cent. Aetiological proportions were similar to these figures for above-knee and through-knee amputees but the Gritti–Stokes amputations were predominantly performed for vascular disease (69 per cent). In the age/duration-matched group, vascular disease was the cause in 61 per cent of above-knee, 38 per cent of through-knee and 71 per cent of Gritti–Stokes amputees. Trauma was responsible in 28 per cent, 54 per cent and 21 per cent, respectively.

A group of vascular amputees was age-matched to ensure that differences in outcome would not merely be a reflection of the cause of amputation. This group included 18 above-knee, 14 Gritti–Stokes and eight through-knee amputees.

Rehabilitation

Fifty-six per cent of patients were satisfactorily rehabilitated as defined by a score of nine or more on the four questions in *Table 1*. This group comprised 47 of 86 above-knee (54 per cent), 34 of 50 through-knee (68 per cent), and 13 of 25 Gritti–Stokes amputees (52 per cent). In the age/duration-matched group, 33 per cent of the above-knee, 62 per cent of the through-knee and 44 per cent of the Gritti–Stokes patients underwent successful rehabilitation. On statistical analysis the through-knee amputees rehabilitated better than the above-knee amputees ($P<0\cdot02$) in both non-matched and matched groups, and better also than the Gritti–Stokes amputees, although this fell short of statistical significance ($P=0\cdot08$). The better rehabilitation of the through-knee amputees was maintained in the group of age-matched vascular amputees. In this group the mean rehabilitation scores were 6·9, 7·1 and 8·3 for above-knee, Gritti–Stokes and through-knee amputees, respectively ($P<0\cdot07$ through-knee *versus* above-knee).

When we looked at the question on stability in isolation, 74 per cent of all above-knee amputees reported being unstable on slopes compared with 28 per cent of through-knee and 56 per cent of Gritti–Stokes. There was less difference on rough ground where 79 per cent above-knee, 65 per cent through-knee and 67 per cent Gritti–Stokes felt unstable.

Wheelchair use

Seventy-nine per cent of our patients never used a wheelchair—86 per cent of above-knee, 68 per cent of Gritti–Stokes and 88 per cent of through-knee amputees. Five patients in each group stayed in a wheelchair all the time. When going outside, seven of the Gritti–Stokes, 11 of the above-knee, and three of the through-knee amputees used a wheelchair. In the age/duration-matched group, both above-knee and Gritti–Stokes amputees were significantly more reliant on their wheelchairs than through-knee patients ($P=0\cdot016$ for above-knee *versus* through-knee, $P=0\cdot05$ for Gritti–Stokes *versus* through-knee). In the age-matched vascular amputees, above-knee amputees

Table 3 *Details of patients without functional use of their limb*

Amputation type	Age	Reasons for not using limb
Through-knee	84	Very heavy and cumbersome
Through-knee	86	Both hips in fixed flexion
Through-knee	72	Other limb deteriorating
Through-knee	83	Recent stroke
Above-knee	90	Ulcer on stump
Above-knee	77	Painful stump
Gritti–Stokes	76	Unable to fit limb (arthritic)
Gritti–Stokes	86	Unable to fit limb

were more reliant on their chairs than through-knee amputees ($P < 0{\cdot}05$). There was little difference between the Gritti–Stokes and the above-knee amputees in any group.

Cosmesis

Our results confirmed some previous reports. The prosthesis used for the through-knee and Gritti–Stokes amputation is essentially the same and was felt to be unattractive in a greater number of cases than the above-knee prosthesis (50 *versus* 31 per cent). As expected, this was a greater problem in women, 75 per cent of whom found the prosthesis unattractive compared with 50 per cent of men

There was no difference between the three groups in terms of local stump problems or the reported frequency of artificial limb repair.

Discussion

The overall number of patients satisfactorily rehabilitated to our rehabilitation score of nine is good (56 per cent). The very high proportion of patients who never use a wheelchair emphasizes that this study is predominantly one of current limb-wearers. The high prevalence of traumatic amputees in this study (48 per cent) is perhaps a reflection of this. The normal incidence of traumatic amputation is 7·9 per cent[13].

We have shown that through-knee amputees rehabilitate better and rely on wheelchairs less than above-knee and Gritti–Stokes amputees. This is in agreement with the results of another recent study[14]. The through-knee amputee is more stable, especially when walking up or down slopes; presumably this is due at least in part to the wide bulbous end-bearing stump of this amputation which is associated with retention of proprioception and greater durability[15] These features of the stump also enable early postoperative mobilization on a pneumatic postamputation mobility aid.

It might be thought that rehabilitation differences could be explained by above-knee amputees being less fit. In this study there were a larger number of vascular patients in the above-knee than in the through-knee group The trend to better rehabilitation of the through-knee amputee in the group of age-matched vascular patients was, however, still present. Moreover, Green *et al* [11], in their study of above-knee and through-knee amputees, found through-knee amputees to be no fitter.

It is noteworthy in our study that above-knee amputees were on average younger at the time of amputation and would therefore be expected to rehabilitate better No trend in this direction is present.

The Gritti–Stokes amputees in this study were more reliant on wheelchairs than the through-knee amputees, an important finding in view of the similar stump length It may reflect lack of stability, either due to a mobile patella or the narrow conical shape of the stump enabling easy rotation of the prosthesis. It should, however, be emphasized that this series included only 27 Gritti–Stokes amputations performed by several different surgeons It would be helpful to do a comparable study on the rehabilitation of a greater number of patients in a centre where this amputation is done frequently. We must also stress that the Gritti–Stokes amputation, with its excellent record for primary healing, is a good amputation for patients not being considered for artificial limbs One problem, concerning both the through-knee and Gritti–Stokes amputation, highlighted in this study is that the prosthesis is unattractive. This is more of a problem in women where the protruding knee may be more obvious and may also cause problems when travelling on public transport.

The through-knee amputation has fallen into disrepute on account of local complications[3,10,11] in the postoperative period. A recent study, however, found this not to be the case[14]. This study used anterior and posterior flaps, although it has been suggested that the utilization of flaps based medially and laterally may give the best results[15].

We do not have information on the perioperative complications in our series or indeed on the number of each amputation type requiring reamputation. Our results suggest that a greater failure and reamputation rate should be accepted with the through-knee amputation, just as with a below-knee amputation The superior rehabilitation with this form of amputation, as with a below-knee, should prompt us to improve both our technique for this amputation and the prostheses currently available.

In the UK in 1985, only 4 per cent of lower limb amputations were at the level of the knee[16]. Our study suggests that the place of the through-knee amputation should be re-examined. It has been shown to give significantly better patient rehabilitation when compared with both the above-knee and Gritti–Stokes amputation. When taking mortality statistics into account, it should be performed instead of an above-knee amputation in cases where either is surgically possible Further studies are needed to evaluate the Gritti–Stokes amputation but our study suggests that successful rehabilitation is less likely than with the through-knee amputation.

Late perfusion, a simple remedy for renal allograft primary non-function?

N.R Parrott, J L.R. Forsythe, T.W.J. Lennard, K.M. Rigg, G Proud and R.M.R. Taylor, *Renal Transplant Unit, Royal Victoria Infirmary, Queen Victoria Road, Newcastle upon Tyne, UK*

The renal transplant with primary non-function presents problems in terms of diagnosis of rejection, dialysis work-load, and duration of hospital stay It is suggested that primary non-function (PNF) is due to the calcium paradox and may be prevented by calcium antagonists The incidence of PNF has been examined in a series of 124 consecutive renal transplants The first 106 patients had *in situ* perfusion alone, and had a PNF rate of 57·5 per cent The second group of patients had identical *in situ* perfusion, but were reperfused immediately before implantation ('late perfusion'). In this group, the PNF rate was 27·8 per cent. The difference was highly significant, $\chi^2=4{\cdot}35$, $P=0{\cdot}035$. The two groups were well matched for age and sex, as well as for donor age, blood pressure and human leucocyte antigen matching. The recipients in the two groups were also well matched for age, blood pressure on clamp release, cold ischaemia, second warm and total ischaemic times, form of dialysis, and transplant number Using stepwise logistic regression, only three factors were significantly associated with PNF. late perfusion ($P=0{\cdot}003$), second warm ischaemia >35 min ($P=0{\cdot}002$), and immunosuppressive agent ($P=0{\cdot}01$). It is concluded that PNF can be alleviated by the simple expedient of 'late perfusion' without recourse to potentially harmful calcium channel blockers.

Apocrine differentiation: a new prognostic factor for breast cancer

N.J. Bundred, R.A Walker, G.K. White, H.J. Stewart and W.R. Miller, *Departments of Surgery and Pathology, University of Leicester and Department of Surgery, Royal Infirmary, Edinburgh, UK*

The importance of apocrine differentiation in breast carcinoma remains unknown An immunoperoxidase method to detect zinc α_2-glycoprotein, an apocrine marker[1], has been used to identify apocrine differentiation in human breast cancers objectively and determine if the expression of differentiation by tumours is of clinical significance.

Breast tumour samples tested from 145 women, with a minimum follow-up of 5 years, were assessed using routinely fixed and processed tissue

Sixty-six (45 per cent) tumours did not stain with the antibody, 52 (36 per cent) exhibited positive apocrine staining whilst 27 (19 per cent) were equivocal. The presence of apocrine differentiation was unrelated to lymph node status, menstrual status, tumour grade or size, oestrogen receptor (E_2R) or progesterone receptor status Patients whose tumours exhibited apocrine staining had a shorter disease free interval (DFI) ($P=0{\cdot}04$) and survival ($P=0{\cdot}05$).

A Cox's multiple regression analysis showed that the presence of staining added significantly to the value of node status ($P=0{\cdot}0002$), menstrual status ($P=0{\cdot}0006$), tumour size ($P=0{\cdot}0008$) and E_2R status ($P=0{\cdot}0004$) in the prediction of DFI and survival. The other seven prognostic factors tested were not statistically significant and were not included in the model.

Apocrine differentiation in breast cancer appears to be an independent predictor of poor-prognosis tumours.

Ileal adaptation following restorative proctocolectomy

W.A. Kmiot, D.J. Youngs, M.C. Winslet, F.T. Curran and M R.B. Keighley, *The General Hospital, Birmingham, UK*

Following restorative proctocolectomy, pouch ileal mucosa undergoes villous atrophy and crypt hyperplasia. To identify concurrent adaptive change in ileal mucosal cell kinetics, we have measured the crypt-cell production rate (CCPR) using a stathmokinetic technique in 15 patients before and 6 months after pouch formation These values were correlated with morphometric estimates of villous height and crypt depth A further CCPR estimate was obtained in the 7 of the 15 patients who had had their pouch defunctioned Validation studies established an organ culture time of 15 h and vincristine dose for metaphase arrest of 4 μg/ml. Linearity of metaphase accumulation was demonstrated for 3 h. Use of three time-points in normal ($n=50$) and pouch ileum ($n=45$) was validated by demonstrating 95 per cent confidence intervals of ±8 per cent and ±10 per cent of the respective means.

The CCPR was significantly higher in pouch ileum, showing a mean (standard error) of 2·49 (0·287) compared with normal ileum 1·35 (0·19), $t=6{\cdot}72$, $P<0{\cdot}01$ There was a decrease in CCPR when the pouch was constructed and defunctioned, with a median (range) of 1·35 (0·5–3·0) *versus* 0·9 (0·5–2·5), $z=2{\cdot}37$, $P<0{\cdot}02$, and a subsequent increase on restoration of intestinal continuity, 0·9 (0·5–2·5) *versus* 2·5 (1·4–4·4), $z=2{\cdot}04$, $P<0{\cdot}05$. An inverse relationship was demonstrated between CCPR and villous height ($r=-0{\cdot}92$, $P<0{\cdot}01$) and a direct relationship with crypt depth ($r=0{\cdot}83$, $P<0{\cdot}05$).

These data demonstrate increased CCPR in pouch ileum and the positively trophic effect of the faecal stream on ileal adaptation

Familial adenomatous polyposis (FAP): gene order at the FAP gene locus with evidence to support the hypothesis that the germ line mutation is sufficient for the development of colonic adenomas

M.G. Dunlop (introduced by A.N Smith), *Medical Research Council Human Genetics Unit, Western General Hospital, Edinburgh, UK*

Genetic linkage for familial adenomatous polyposis (FAP) has recently been established with probes C11P11 (Reference 1) and pi227 (Reference 2), mapping to chromosome 5q21–22 Gene ordering has not yet been possible but has important clinical and scientific implications Linkage analysis of six FAP families, including 111 genotyped and phenotyped individuals, is reported. Two C11P11–FAP and two pi227–FAP obligate recombinants were identified. One was recombinant for both, locating C11P11 and pi227 on the same side of the FAP locus. A further probable C11P11–FAP and pi227–FAP recombinant was detected Lod scores were calculated[3] to estimate genetic distances for each probe (peak Lod score for C11P11 of 5·57 at recombination fraction 0·07; and for pi227, 3·49 at 0·11), placing C11P11 closest to FAP. Gene order is therefore pi227–C11P11–FAP

Having identified C11P11 as the closest marker to FAP, the hypothesis that the germ line mutation is sufficient for the development of colonic adenomas[1,4] was tested by a search for gene loss No loss for C11P11 constitutional heterozygosity was found in 19 adenomas from three FAP patients, suggesting preservation of the FAP gene on the normal chromosome 5. Therefore it appears that haploid insufficiency of the FAP gene allows adenomatous change in the colonic epithelium

Flow cytometric analysis of ductal carcinoma-in-situ (DCIS) of the breast

A.P. Locker, C.S. Dowle, C. Horrocks, A.S. Gilmour, I O. Ellis, C.W. Elston and R.W. Blamey, *Nottingham City Hospital, Nottingham, UK*

With the introduction of screening for breast cancer, DCIS has become a more common management problem The clinical behaviour of DCIS depends on histological type. Tumour DNA content relates to histological grade and clinical course in invasive breast cancer[1]

Of 74 patients with DCIS (follow-up from 18 to 144 months), eight have developed local recurrence. These were from 55 solid or mixed DCIS type; none of 15 cribriform tumours have recurred

Flow cytometry was used on paraffin-embedded tumours DNA indices and S-phase content were derived from these histograms

0007-1323/89/060625-25$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Tumours were graded histologically according to mitotic index and pleomorphism The median S-phase was 3 per cent for the cribriform cancers and 11 per cent for the solid and mixed DCIS.

Table 1

Tumour type	Diploid/near diploid	Aneuploid
Cribriform	13	2
Mixed	8	15
Solid (including Comedo)	16	16
Papillary	1	3

$\chi^2=11{\cdot}15$ (3 d f.); $P<0{\cdot}02$

Table 2

	Histological grade		
Tumour type	1	2	3
Cribriform	14	1	0
Papillary	3	1	0
Mixed	9	10	4
Solid (including Comedo)	2	5	25

$\chi^2=67{\cdot}63$ (6 d f.); $P<0{\cdot}001$

These biological parameters considered together with our clinical observations suggest that cribriform DCIS is less aggressive than other types of DCIS, with important implications as to its management

Is the multiple drug resistant gene (mdr-1) important in determining response to Adriamycin® in breast cancer?

S. Stallard, R. Brown, N. Keith, W.D George* and J.A. Bradley*, *Departments of Medical Oncology and *Surgery, Western Infirmary, Glasgow, UK*

Resistance to chemotherapy is a major cause of treatment failure in breast cancer Recent *in vitro* evidence suggests that one mechanism by which leukaemic and other cell lines develop drug resistance is the over-expression of a cell-membrane glycoprotein p180 encoded by the *mdr*-1 gene. In this study 30 freshly excised human primary breast cancers were examined to determine whether they expressed the *mdr*-1 gene and whether this related to their drug resistance to Adriamycin® (Farmitalia Carlo Erba, UK)

The mRNA was extracted from tumour tissue and *mdr*-1 gene expression was analysed by molecular hybridization to an *mdr*-1 probe. Quantitative analysis was performed by standardization of the results to a constantly expressed gene (β_2-microglobulin) and to total mRNA levels by hybridization to poly d (T). Chemoresponsiveness was measured by an *in vitro* colony-forming assay on tumour cells grown in short-term culture and expressed as the dose of Adriamycin causing 50 per cent inhibition of growth (ID_{50}).

All breast tumours were found to express the *mdr*-1 gene but the levels of gene expression varied widely (100-fold variation) between different tumours Glycoprotein p180 mRNA levels showed an inverse correlation with tumour sensitivity to Adriamycin ($r=-0{\cdot}71, P<0{\cdot}05$) These results support the hypothesis that the *mdr*-1 gene may play a role in determining the response of human breast cancer cells to chemotherapy.

Intraperitoneal production and systemic transfer of lymphokine-activated killer cells (LAKC) for treatment of disseminated gastrointestinal adenocarcinoma

D.H. Johnston, N.S. Williams, A.C Newland, M G. Macey, M. Turkish, P. O'Byrne, P. Durdey, J.Th. Bijman and G.R. Franks, *Departments of Surgery and Haematology, The London Hospital, London, UK*

Combined systemic therapy with recombinant interleukin 2 (rIL-2) and *in vitro* generated LAKC achieves responses for some advanced solid tumours, but toxic effects limit its use and treatment cost is prohibitive We have studied LAKC response after intraperitoneal infusion of lymphocytes from leukapheresed peripheral blood (LPBL) and rIL-2, and peritoneovenous transfer of LAKC by Denver ($n=5$) or Leveen ($n=1$) shunt. Incremental dosage of rIL-2 was administered by intraperitoneal infusion over 10 days ($11{\cdot}5$–$1{\cdot}35\times10^5$ units/kg per 24 h) Mild pyrexia ($n=6$), malaise ($n=6$), and anorexia and nausea ($n=3$) were observed. Abdominal discomfort ($n=2$) was controlled by non-opiate analgesia and five patients remained ambulant throughout treatment. Although lymphopenia and anaemia were evident, capillary leak syndrome did not occur Lymphocyte subset markers and natural killer activity to K562 targets (NKA) were studied serially by flow cytometric analyses.

Peritoneal	Day 1 mean (s e m)	Day 10 mean (s e m)	Paired *t* *n*
Helper:suppressor (CD4.8 ratio)	1·5 (0·4)	3·2 (0·6)	5 ($P<0{\cdot}01$)
IL-2 receptor + (CD25) proportion	1·9 (0·6)	21·6 (4·9)	5 ($P=0{\cdot}02$)
NKA (percentage killed)	8·8 (2·8)	47·7 (16·2)	4 ($P=0{\cdot}07$)
Peripheral blood NKA	8·7 (2·7)	25·3 (7·3)	3 ($P=0{\cdot}2$)

Repeated monthly treatments were possible ($n=4$, currently 2,2,3,7 cycles) Using this new technique a LAKC response can be induced within the peritoneal cavity and appears to be transferred into the systemic circulation It is cheap and well tolerated compared with systemic immunotherapy using *in vitro* generated LAKC, and may have the potential to revolutionize this type of treatment

Is there an increased risk of breast cancer in women who have a breast cyst aspirated?

N.J. Bundred, R R. West, J. O'Dowd and R.E. Mansel, *Departments of Surgery, Pathology and Community Medicine, University of Wales College of Medicine, Cardiff, UK*

Clinical studies suggest women who have breast cysts aspirated have an increased risk[1] of breast cancer but histologists claim only women with proliferative breast lesions are at risk[2]

A consecutive series of 644 women presenting with breast nodularity from 1976 to 1982 have been traced to determine their rate of subsequent breast cancer. 14 per cent had undergone breast biopsy. Five women had cancer diagnosed within a year of presentation and were excluded from further analysis The remaining 639 women fell into two groups, those with and those without a breast macrocyst which could be aspirated Ninety-one per cent of women have been followed up for 5 years or more (4129 women-years).

Age-specific person-years at risk were multiplied by national age-specific cancer registration rates (Office of Population Census Studies, 1983) to obtain an expected cancer incidence. Fifteen women have developed breast cancer, which is an excess risk in the macrocyst group of 5·8 times those with no macrocysts. Women with breast nodularity had no excess risk compared with expected incidence (see *Table*). Review of biopsy specimens revealed more epitheliosis in women with macrocysts ($P<0{\cdot}005$)

Macrocysts are clinical markers of histological proliferative breast lesions. Women who have had breast macrocysts aspirated have an increased risk of breast cancer and should be followed up.

		Cancers		
Diagnosis	*n*	Expected	Observed	Relative risk*
No macrocysts	287	1·1	1	1
Macrocysts aspirated	352	2·4	14	5·8

* Exact binomial test ($P<0{\cdot}001$)

A new technique of colonic re-epithelialization by fenestrated ileal mucosal autografts

F C. Campbell and D.A. Hopwood, *Departments of Surgery and Pathology, Ninewells Hospital, Dundee, UK*

In short bowel syndrome (SBS) the colon is often normal, but absorbs little This study has devised and tested a method of expanding absorptive ileal mucosa into the colon

A fenestrated ileal mucosal graft is prepared from a 12-cm isolated loop, with intact vascular pedicle. The loop is denuded of muscle, fenestrated with opposing interdigitating incisions 1·5 cm apart, expanded to 20 cm, then grafted into a 20 cm loop of colon which has been stripped of its mucosa. Assessment of (1) graft 'take', (2) re-epithelialization time of fenestration, and (3) new mucosal architecture, was carried out in five test pigs. New mucosal function (4) was assessed by histological evaluation of fatty acid absorption, against normal ileum, of three control pigs

Successful graft 'take' occurred in all the four surviving test pigs. Re-epithelialization of all fenestrations (and the whole colonic loop) was complete in test animals by 5 weeks (healing time (s.d.)=3·8 (1·5) weeks). New mucosa was initially flat. At 8 weeks, villous architecture was restored but electron microscopy suggested persistent cellular immaturity. Fatty acid absorption by new grafted mucosa was indistinguishable from control ileal mucosa.

It was concluded that viable ileal mucosa can be harvested into colon, with a 66 per cent expansion of its surface area, with recovery of architecture and function. This method appears promising as a surgical approach to SBS.

A neosphincter for the treatment of faecal incontinence

N.S. Williams, R.I. Hallan, T. Koeze* and E.S. Watkins*, *Surgical Unit and *Neurosurgical Unit, The London Hospital, London, UK*

Patients with faecal incontinence in whom the conventional operations fail, or are contraindicated, may be treated by a gracilis sling procedure This operation is, however, rarely performed as the results are unpredictable. Chronic electrostimulation of the transposed gracilis has the theoretical advantage of converting the fast-twitch muscle to a slow-twitch muscle capable of fatigue resistance Such a property is vital if the muscle is to act as a sphincter.

Seven patients whose only alternative was a permanent stoma were treated by a gracilis sling procedure and implantation of a permanent electrostimulator (Medtronic) All patients had a covering stoma, and six were stimulated at 2–10 Hz continually for a minimum of 6 weeks. Manometry and a saline stress test were performed and fusion frequency was determined before and after stimulation (stim).

$n=5$	Without stim*	With stim	Paired t test
Maximum sphincter pressure (cmH$_2$O)	19·6±2·5	40·2±5·1	$P<0{\cdot}02$
Saline stress test· volume to leak (ml)	48·9±12·5	80·1±22·5	$P<0{\cdot}05$
	Pre-stim	After 6 weeks stim	
Fusion frequency (Hz)	24·6±0·4	17·3±1·2	$P<0{\cdot}001$

*Mean ± s.e.m.

These results indicate that electrical stimulation of the transposed gracilis muscle enhances its power to achieve continence. Furthermore chronic stimulation converts it to a slow-twitch muscle capable of contraction without fatigue This new technique should improve the results of the gracilis sling procedure but it remains to be seen how these patients will fare after their stomas are closed.

Is digital rectal examination a good guide to anal pressure?

A.W. Hall, M.J.G. Watkins, H.S. Hall and H.J. Pearson, *Departments of Surgery, University of Leicester and Department of Medical Physics and Clinical Engineering, Leicestershire Health Authority, Leicester, UK*

During assessment of patients with anorectal problems, anal tone is usually estimated on digital rectal examination As major treatment decisions are often made on this basis, the relationship of such empirical judgements to anal pressure is important

Fifty-three patients with various anorectal disorders were referred for detailed assessment. Immediately before the study each was examined by an experienced surgeon Anal tone was classified as poor/absent, normal or increased Whether the anus was closed or gaping was also noted. The anal pressure profile was determined using a 5 mm, balloon-ended catheter and a station pull-through technique. The maximum resting pressure was noted

Nineteen patients had poor or absent anal tone. Anal pressure in these varied from 14 to 132 cmH$_2$O (median 31). In 29 subjects assessed as 'normal' the range was 6·8–156 cmH$_2$O (median 82) and where tone was thought high, the range was 136–177 cmH$_2$O (median 149·6) Although each of these groups differs significantly ($P<0{\cdot}02$) there is considerable overlap. The anus was gaping in 17 subjects and closed in 34 (in two patients this was not recorded). The pressure profiles were 6·8–156 cmH$_2$O (median 31) and 13·6–177 cmH$_2$O (median 88·4) respectively Again the difference is significant ($P<0{\cdot}02$) but the overlap considerable.

Physical examination whether by finger or appearance was therefore shown to give a very poor assessment of anal pressure.

Defunctioned proctitis: a diagnostic dilemma

M.C. Winslet and M.R.B. Keighley, *The General Hospital, Birmingham, UK*

Proctitis in the defunctioned rectum may represent a normal physiological response or the onset of inflammatory bowel disease It is a common indication for not restoring intestinal continuity The aim of this study was to investigate the cause, diagnostic criteria and effect of restoring intestinal continuity in this condition.

Eighteen patients underwent diversion and 10 had intestinal continuity restored for a non-inflammatory condition. Macroscopic inflammation occurred in 10 patients (56 per cent) within 3 months of diversion, with histological confirmation in five. Five patients showed macroscopic and histological improvement on restoring continuity There was no significant difference in mucosal indices between the proctitis (P) and non-proctitis (NP) group. (Crypt-cell production rate: P=2·5±0·7, NP=2·9±0·9 cells crypt^{-1} h^{-1}. Glucosamine synthetase. P=14·3±3·3, NP=14·7±2·6 mmol g^{-1} h^{-1}. Mucosal lymphocytes. P=1·1 × 10^{7}, NP=1·9 × 10^{7} cells g^{-1}) The flora of the excluded colon (aerobic and anaerobic species carriage rate· organisms (P=6·8^{7}, NP=3·0^{7}) and species count (P=4, NP=4)) was not significantly different in the two groups. Colonic permeability was similar (P=8·5 per cent, NP=6·1 per cent).

Defunctioned proctitis is a common complication after faecal diversion of unknown aetiology Its only diagnostic feature, to date, is resolution after restoration of continuity. Its presence is not a contraindication to stoma closure.

Function after stapled ileal pouch–anal anastomosis for ulcerative colitis

D. Marzouk, N.S. Williams and R.I Hallan, *Surgical Unit, The London Hospital, London, UK*

Mucosal proctectomy and endoanal ileal pouch–anal anastomosis leads frequently to minor leakage which has been attributed to internal sphincter damage, presumably from prolonged anal retraction A stapled pouch–anal anastomosis does not stretch the sphincter and should lead to better function

Eleven patients with ulcerative colitis (six men and five women) with a median age of 31 years (range 17–53 years) underwent ileal pouch formation and construction of a stapled anastomosis by a modified technique, which eliminated the use of purse-string sutures. Manometry and clinical evaluation were performed before and 3 months and 9 months after operation, respectively. Function was compared with our previous results achieved with mucosal proctectomy and endoanal anastomosis. Stapled pouch anastomosis was quicker to perform (3 h *versus* 5 h), but bowel frequency (6/24 h), and requirement for medication (nine patients, 90 per cent) were similar to those achieved after proctectomy and endoanal anastomosis. Continence was only marginally superior, with seven patients entirely continent, two with occasional nocturnal leakage and two with moderate leakage. The resting anal pressure and maximum squeeze pressures were 75 (52–110) and 140 (26–350) cmH$_2$O, respectively, before operation, and 34 (20–60) cmH$_2$O ($P<0{\cdot}01$, Mann–Whitney U test) and 93 (14–190) cmH$_2$O after operation, the latter figure being not significantly different

Thus, although a stapled anastomosis is quicker to perform than the conventional technique, and may lead to improved continence, it causes damage to the internal anal sphincter This must be due to a mechanism other than anal retraction. Further functional improvement is only likely if this damage can be identified and avoided.

Faecal challenge as a predictor of the effect of restoring intestinal continuity in defunctioned Crohn's colitis

M.C. Winslet and M.R.B. Keighley, *The General Hospital, Birmingham, UK*

The effect of restoring intestinal continuity in patients with defunctioned Crohn's colitis is unpredictable. The aim of this study was to assess whether preoperative faecal challenge of the defunctioned colon with ileostomy effluent can predict those patients likely to suffer an early relapse.

Nine patients (four men and five women, mean age 39 years) with Crohn's colitis, admitted for restoration of intestinal continuity, had a mean volume of 120 ml (range 60–280) ileostomy effluent inserted into the efferent limb of their loop ileostomy daily for 7 days. The time to defaecation was 1(1–2) day. Four patients developed diarrhoea (5–10 times a day) with systemic symptoms and were considered unsuitable for stoma closure. Two patients developed mild diarrhoea whilst three were asymptomatic. Five patients had intestinal continuity restored and all remain in clinical remission at 6 months.Changes in serum and mucosal indices of disease activity after faecal challenge and restoration of continuity was similar. Faecal challenge produces results similar to restoration of intestinal continuity. It is a useful method of predicting patients likely to suffer an early relapse in whom intestinal continuity should be avoided.

	Defunctioned	Faecal challenge	Intestinal continuity
Modified activity index	99±7	118±8*	115±6*
Albumin (g/l))	40·7±1·2	39·5±1·3	398·8±1·0
α_1-Antichymotrypsin (g/l)	0·65±0·1	0·77±0·1	0·8±0·1****
α_1-Acid glycoprotein (g/l)	1·07±0·2	1·31±0·2*	1·46±0·2****
Glucosamine synthetase (mmol/g wet weight per day)	16·5±2·7	28·1±4·9***	28·5±4·6**

* $P<0.05$; ** $P<0.02$, *** $P<0.01$; **** $P<0.001$

A clinical index to assess treatment of perianal Crohn's disease

A. Allan, L. Linares and J. Alexander-Williams, *Department of Surgery, The General Hospital, Birmingham, UK*

The treatment of the perianal complications of Crohn's disease is empirical and the results are assessed subjectively. A simple clinical index of perianal Crohn's disease (PACD) would allow quantification of the efficacy of surgery or medical treatments.

Forty patients with PACD and 14 patients with other anal pathology were studied. A linear analogue score (LAS) was used to record seven clinical parameters before and after surgical treatment. These included perianal pain, pruritus ani, inhibition of locomotion, social and sexual activity, pain on defaecation and anal leakage. The Mann–Whitney *U* test was used to determine differences in LAS before and after treatment.

Therapy	Number of patients	LAS before treatment	LAS after treatment
Patients with PACD			
Drain perianal abscess	25	3·9 (1·9–6·4)	0·6 (0–5·7)‡
Other minor anal surgery	7	3·3 (2·3–5·3)	1·6 (0–2·0)‡
Loop ileostomy or proctectomy	5	2·4 (1·6–6)	0 (0·04)†
Continual drug therapy	3	2·3 (2·3–2·5)	0·4 (0·3–1·4)§
Patients with other anal pathology			
Haemorrhoidectomy	10	2·8 (1–4·8)	0·2 (0–0·8)†
Drainage of perianal abscess	4	4·6 (1·2–7·2)	0·2 (0–1·2)*

Results are shown as median (ranges)
* $P<0.05$, † $P<0.01$, ‡ $P<0.001$, § not significant

This simple clinical index of PACD is sensitive to changes in disease state brought about by surgical or medical therapy. It has potential for prospective comparison of rival treatments of PACD.

The role of the faecal stream in maintaining the inflammatory process in Crohn's colitis

M.C. Winslet, A. Allan and M.R.B. Keighley, *The General Hospital, Birmingham, UK*

The remission rate in Crohn's colitis treated by ileostomy alone (82 per cent, $n=44$) implicates a faecal constituent in disease pathogenesis. Faecal diversion provides an alternative to resection and also a model to investigate the role of the faecal stream. The effect of diversion and restoration of continuity on clinical (MDAI), blood (haematological/acute phase proteins) and mucosal (histological/cell birth rate/mucous-Ig production glucosamine synthetase activity) indices of disease activity was assessed in patients with Crohn's colitis (diversion 22, continuity 10) and in controls with a non-inflammatory condition (diversion 13, continuity 8) with reference to changes in colonic microflora and permeability.

In Crohn's colitis, after faecal diversion there was a fall in MDAI from 176±9 to 114±9 ($P<0.01$); in acute phase proteins from 1·9±0·2 to 1·1±0·1 g litre^{-1} ($P<0.01$), and in glucosamine synthetase activity from 31·9±3·4 to 24·8±3·6 mmol g^{-1} h^{-1} ($P<0.01$). Restoration of continuity produced an increase in acute phase proteins from 1·1±0·1 to 1·5±0·2 ($P<0.05$) and in glucosamine synthetase activity from 14·7±2·6 to 27·3±3·7 ($P<0.01$). There was no difference in the mucosal/luminal qualitative or quantitative aerobic/anaerobic flora after faecal diversion. Colonic permeability (^{51}Cr-EDTA) increased from 6·2±2·7 to 27·8±4·2 per cent ($P<0.05$) after faecal diversion.

This study implicates the faecal stream in the inflammatory mechanism of Crohn's colitis. It suggests that post-diversion remission is mediated by exclusion of a non-bacterial component. Faecal challenge of the defunctioned colon may determine the role of individual constituents.

Percutaneous angioscopic assessment of the immediate effects of laser and dynamic angioplasty in total peripheral arterial occlusions

S. Ashley, A.A. Gehani, G.A. Davies, R.C. Kester and M.R. Rees, *Cardiac Research Unit, Killingbeck Hospital, Leeds, UK*

High-resolution, ultrathin, flexible fibreoptic angioscopes (Olympus PF 1·4 mm and 1·8 mm outer diameter), have been used via a No. 8 Fr percutaneous angiographic guiding sheath, to assess the immediate effects of angioplasty in 10 patients with 12 total peripheral arterial occlusions. This group included three patients with reocclusions following previous angioplasty procedures. There were 10 femoral and two iliac lesions, ranging from 1 to 15 cm in length. Angioplasty was performed with either a No. 8 Fr fast-rotating tip atherectomy catheter (Kensey) ($n=6$), continuous wave Nd-YAG laser (Surgical Laser Technologies CL 60) delivered by fibres with 2·2 mm hemispherical sapphire distal tips ($n=3$), or balloon angioplasty alone ($n=3$). A clear view was successfully obtained in 10 out of 12 vessels by displacing flowing blood with a pressurized heparin/saline flush. The total volume of fluid administered intra-arterially ranged from 300 to 1000 ml. A video recording of each procedure was made via a micro-chip camera (Olympus OTVF).

Angioscopy was performed to identify intimal flaps after all angioplasty procedures. After mechanical angioplasty in two patients, the detection of large obstructive flaps led to additional laser therapy to improve blood flow. Angioscopy has demonstrated effective percutaneous laser ablation of thrombus and atheromatous plaque. Small areas of intimal charring were seen after laser delivery, but there were no vessel-wall perforations. Angiography was undertaken in all patients and compared with angioscopy. The above features were either not demonstrated or poorly demonstrated by angiography. There were no embolic complications or problems related to fluid overload.

Thermographic and electron microscopic analysis of integral optical fibre tips for pulsed laser angioplasty

A. Murray and R.F.M. Wood, *Surgical Unit, St Bartholomew's Hospital, London, UK*

Studies of laser angioplasty with the metal-capped ('hot-tip') probe have shown that the tip temperature of 400°C produces widespread thermal damage. To overcome this we have developed an integral spherical tip to be used with pulsed lasers. This study defines their thermal characteristics.

An Agema Thermovision-870 infrared camera imaged a series of six fibreoptic probes in air and during laser ablation of arterial wall *in vitro*. Each probe comprised a 2 m length of 0·6 mm diameter quartz expanded into a 2·5 mm sphere, three were precision ground to produce a 2 mm diameter flat face. Laser energy was produced by a Pulsed Dye laser (wavelength 480 nm, 1 μs pulses). The peak temperature reached only 48°C in air and that of the ground tip was significantly less than that of the spherical ($P<0.01$), though the reverse was found when ablating arterial wall ($P<0.01$). This difference was lost when the laser tip was in direct tissue contact. The highest temperatures were attained with atheroma (130°C). After prolonged use of the laser with the tip in contact, tips attained higher temperatures in air than when new. Scanning electron microscopy revealed surface pitting and fissuring in these cases Initial temperature characteristics were regained after regrinding The surface damage of the tip is likely to be due to plasma production associated with pulsed ablation, leading to light scatter and higher tip temperatures

We conclude that use of the pulsed laser with integral fibre tips does not attain the excessive temperatures reported with metal-capped probes and will therefore minimize vessel wall damage and lessen the risk of perforation.

A vein collar/patch optimizes patency rates in PTFE grafts

M.R. Tyrrell, J.F. Chester*, R.S Taylor* and J.H.N. Wolfe, *St. Mary's Hospital and Irvine Cardiovascular Laboratory, London and *Epsom District Hospital, Surrey, UK*

The results of polytetrafluoroethylene (PTFE) grafts to crural vessels have been sufficiently poor for some surgeons to consider primary amputation for critical ischaemia in the absence of suitable autologous vein. However, the results of two anastomotic techniques using a short segment of interposed vein[1,2] are encouraging

We have attained 1-year actuarial patency rates of 47 per cent ($n=27$) using PTFE with Miller collar anastomoses to distal crural vessels, and 84 per cent ($n=45$) using the Taylor patch technique[3]

To investigate the haemodynamic benefit of these techniques, we have tested them (using a pulsatile flow model[4] incorporating standard pressure, viscosity, graft and vessel length, and anastomotic angle) against a standard end-to-side PTFE anastomosis to cadaveric internal mammary artery There was no significant difference in flow between the anastomotic methods. Downstream resistance was dictated by the diameter of the vessel, provided a vein interposition technique was used ($r>0·70$), but this relationship was lost if a direct PTFE/arterial anastomosis was performed ($r=0·04$), suggesting additional anastomotic resistance in the latter.

In conclusion, this constitutes experimental evidence to support the hypothesis that these vein-interposition techniques confer haemodynamic benefit in the use of PTFE.

The effects of cigarette smoking, carbon monoxide and nicotine on the uptake of ^{125}I-labelled fibrinogen by the canine arterial wall

D.R. Allen, N.L. Browse and D.L. Rutt, *St Thomas' Hospital, London, UK*

Permeability of the arterial wall of anaesthetized dogs has been shown to be increased by inhaling cigarette smoke or carbon monoxide (CO) but not by intravenous nicotine. These experiments describe the effect of cigarette smoke, CO and nicotine on the amount of ^{125}I-labelled fibrinogen retained within the arterial wall.

Four groups were studied: a control group (6 arteries); a smoking group (6 arteries) who inhaled 20 cigarettes over 5 h; a carbon monoxide group (8 arteries) who inhaled 400 p.p.m CO over 5 h, and a nicotine group (8 arteries) who received intravenous nicotine 2·5 μg kg^{-1} min^{-1} for 5 h. Carboxyhaemoglobin, plasma nicotine and arterial pressure were monitored in all groups Two hours after commencing the experiment, ^{125}I-labelled fibrinogen was injected intravenously Plasma radioactivity was recorded every 30 min for 3 h to calculate plasma decay. A 3 cm length from each carotid artery was then excised, the adventitia removed and, after homogenization, the artery wall was resuspended in 2 ml saline and radioactivity counted in a well-counter. Wall uptake was calculated by dividing the wall count by the plasma count.

	Control	Smoking	CO	Nicotine
Wall uptake units × 10^{-4} ± s.e.m.	4·5 ± 1·4	5·5 ± 2·8	6·1 ± 2·7	9·1 ± 2·1

$P<0·001$ (unpaired t test)

The results showed that whereas intravenous nicotine did not increase the permeability of the arterial wall to fibrinogen, it did increase the amount of fibrinogen retained within the arterial wall

Is thrombocytopenia after aortic surgery related to salvage autotransfusion?

J.F. Thompson, the late P.C. Clifford, J.H.H. Webster and A.D B. Chant, *Vascular Unit, Royal South Hants Hospital, Southampton, UK*

Haemostasis is dependent on adequate numbers of functional platelets A transient fall in platelet numbers has been described following salvage autotransfusion (ATS)[1] and platelet activation occurs during cardiopulmonary bypass[2] ATS involves extracorporeal circulation and these factors may be implicated in postoperative bleeding

To investigate these effects 50 consecutive patients (mean age 69 years) undergoing elective aortic reconstruction have been studied. Twenty received bank blood (controls), 20 ATS (non-washed) and ten ATS (cell-saver).

Blood samples were taken preoperatively and at 0 h, 4 h, 24 h and 1 week postoperatively Platelet counts were performed using a laser particle counter. To measure the overall integrity of the haemostatic mechanism, template bleeding times (Simplate-II, single observer, with venous occlusion) were performed preoperatively and at 4 h. This avoided the contribution of residual heparin and anaesthetic agents

There was no morbidity related to postoperative bleeding.

Table 1 *Platelet count*

	Platelets × 10^9 litres (mean and s.e.m.)		
	Controls	Non-washed	Cell-saver
Preoperative	244 (16·4)	250 (11·0)	216 (12·4)
0 h	175 (10·4)	172 (13·0)	158 (17·0)
4 h	149 (10·2)	165 (13·0)	169 (25·0)
24 h	131 (9·6)	145 (9·8)	135 (11·8)
1 week	221 (18·0)	280 (18·0)	228 (10·0)

All differences non-significant by Wilcoxon test

Table 2 *Bleeding times*

	Controls (s)	Non-washed (s)	Cell-saver (s)
Preoperative	207 (15·9)	226 (24·0)	195 (16·0)
Postoperative	301 (18·3)	314 (24·2)	270 (27·7)

Salvage ATS does not appear to contribute appreciably to the fall in platelet count seen after aortic surgery In this series, ATS by either technique did not give rise to a significant bleeding diathesis.

Prazosin reduces the development of atherosclerosis in rabbit aorta

M.K. O'Malley, D. Hehir, J. O'Byrne, D. Mehigan and N.J. O'Higgins, *Department of Surgery, University College, Dublin, Ireland*

Earlier studies have demonstrated that prazosin, a selective α_1-adrenergic antagonist, reduces the development of intimal hyperplasia in rabbit aorta[1]. Intimal hyperplasia is thought to be a precursor for atherosclerosis and so we have examined the effect of prazosin on atherogenesis Atherosclerosis was induced in 32 New Zealand white rabbits with a 1 per cent cholesterol diet either alone or in combination with endothelial denudation of the aorta using a Fogarty balloon catheter. Test rabbits were given 4 mg prazosin orally commencing on the morning of surgery and continuing until they were killed 8 weeks later The aortas were then harvested, opened longitudinally and stained with Sudan IV to demonstrate atherosclerotic plaques. Photographs of the intimal surface were enlarged and an x–y digitizer was used to measure the percentage of aortic intima affected by atherosclerosis.

	Diet alone ($n=8$)	Diet + prazosin ($n=8$)	Diet + denudation ($n=8$)	Diet + denudation + prazosin ($n=8$)
Percentage aortic atherosclerosis (mean ± s.e.m.)	38·8 ± 6·2	28·1 ± 3·1	60·5 ± 2·3	49·3 ± 4·3
	P = n.s.		$P<0·05$	

The results show that prazosin significantly reduces the development of atherosclerosis in denuded rabbit aorta and may also reduce atherogenesis in normal rabbit aorta. These results further support the use of prazosin in reducing the complications of endothelial denudation[1,2].

Non-invasive determination of concomitant coronary artery disease in patients with intermittent claudication

A-M. Salmasi and A.N. Nicolaides, *Irvine Laboratory for Cardiovascular Investigation and Research, Academic Surgical Unit and Vascular Unit, St. Mary's Hospital Medical School, London, UK*

The association between intermittent claudication and concomitant coronary artery disease (CAD) is well recognized. The ECG chest wall mapping stress test (CWM), which can detect the presence of coronary artery disease in individual coronary artery territories[1], has been used in 100 consecutive patients with intermittent claudication. ECG recordings from all the leads were carried out at rest, each minute during exercise, at peak exercise and each minute after terminating the exercise until the heart rate and blood pressure returned to pre-exercise values. Areas of significant ST segment changes (elevation or depression), inverted U-waves and resting Q-waves were determined and assigned to individual coronary artery territories.

The exercise testing was positive in 47 patients. It suggested significant single coronary artery disease in six, double in 16 and triple in 25 patients. Coronary arteriography was carried out in 34 of 47 patients with a positive stress test. Significant CAD (>50 per cent stenosis in at least one coronary artery) was present in all the 34 patients. The predictive accuracy of CWM to detect the number of coronary arteries with significant stenosis was 84 per cent while the predictive accuracy in diagnosing a significant lesion in an individual coronary artery territory was 92 per cent. On clinical grounds the presence of CAD was suspected in 21 of the 47 patients with a positive stress test. Thus, occult CAD was present in 26 patients, which was confirmed later by coronary arteriography; 12 of these had significant disease in three coronary artery territories. The results confirm the high incidence of severe coronary artery disease in claudicants and indicate the values of this non-invasive screening test in patients with intermittent claudication.

Erythrocyte fatty acid changes in the diagnosis and postoperative follow-up of patients with colorectal carcinoma

S.B. Kelly, N.A. Habib, M. Lucarotti, J. Beynon, C.B. Wood* and R.C.N. Williamson*, *Departments of Surgery, Bristol Royal Infirmary* and **Royal Postgraduate Medical School, London, UK*

The stearic to oleic acid ratio (saturation index) of erythrocytes has been found to be significantly lower in patients with malignant disease compared with patients with benign diseases and normal healthy subjects. Similar changes have also been observed in solid tumour tissue and leukaemic cells. The aim of this study was to investigate whether the erythrocyte saturation index could be useful as a marker for patients with colorectal carcinoma. Blood samples were obtained from normal healthy subjects and patients with colorectal carcinoma, recurrent colorectal carcinoma, inflammatory bowel disease, and benign colonic polyps. Total lipids were extracted from the erythrocytes and the fatty acids were analysed by gas–liquid chromatography. The ratio of stearic to oleic acid was taken as the saturation index (SI).

Group	Number	SI mean ± s.e.m.
Normal subjects	107	1·18 ± 0·02
Inflammatory bowel disease	18	1·25 ± 0·06
Benign colonic polyps	18	1·20 ± 0·06
Colorectal carcinoma	97	0·97 ± 0·02
Recurrent colorectal carcinoma	21	1·01 ± 0·05

This study confirms that the erythrocyte saturation index is lower in patients with colorectal carcinoma ($P<0·001$) and recurrent colorectal carcinoma ($P=0·003$–$0·01$) than in normal healthy subjects or patients with various benign diseases. In addition, the index returns to normal (mean 1·14 ± 0·03, $n=33$) at 3 months postoperatively in patients who remain disease-free following curative resection ($P<0·001$). Thus, the erythrocyte saturation index may be useful in the diagnosis and postoperative monitoring of patients with colorectal carcinoma.

Tumour cell-mediated suppression of lymphokine-activated killer cell generation is associated with the release of soluble suppressor factors from tumour cells

S.S. Somers, C.W. Ramsden, P.C. Sedman and P.J. Guillou, *University Department of Surgery, St James's University Hospital, Leeds, UK*

Adoptive immunotherapy of patients with metastatic tumour using autologous lymphokine-activated killer (LAK) cells and interleukin 2 (IL-2), is successful in only 40 per cent of patients. The impaired LAK generation in patients with advanced disease may be due to direct interference with LAK stimulation by tumour cells, as therapy with IL-2 alone is ineffective.

The possible immunosuppressive effects of tumour-cell products were investigated using serum-free supernatants from the following cell lines: G361 (melanoma), COLO 205, COLO 320, HT-29 (colorectal cancers), MiPaCa (pancreatic cancer), SKBr3 (breast cancer), WISH (human amnion) and normal endothelium. Normal human peripheral blood mononuclear cells were incubated for 4 days with 1000 units/ml IL-2 in the presence of 20 per cent supernatant from an individual cell line. LAK cytotoxicity (lytic units) was measured on the fourth day of culture. The results are shown in the *Table*.

Source of supernatant	Target cell	Inhibition of lytic units (%)
G361	G361	99·9
COLO 320	COLO 320	62·1
COLO 205	COLO 205	99·9
HT-29	G361	99·9
MiPaCa	G361	92·1
SKBr3	SKBr3	−3·0
WISH	SKBr3	−40·0
Normal endothelium	SKBr3	−5·0

This suppression of LAK generation was time-related and dose-related. Generation of LAK cytotoxicity was inhibited by supernatant concentrations as low as 5 per cent but inhibition of proliferation was only seen with higher concentrations. The inhibitory component is stable on heating to 56°C but not to 70°C, is acid-labile and has a molecular weight greater than 25 000. The metabolic inhibitors mitomycin C, Adriamycin® (Farmitalia Carlo Erba, UK) and cycloheximide, diminish the production of the suppressive component by cell lines. Tumour cell-mediated inhibition of LAK cell function may, in part, explain the therapeutic failure of adoptively transferred LAK cells and IL-2 in humans.

Microendoscopy in the diagnosis of anal dysplasia

J.H. Scholefield, C. Sonnex, C. Whatrup and J.M.A. Northover, *ICRF Unit, St. Mark's Hospital and The Middlesex Hospital, London, UK*

Evidence that sexually transmissible types of human papillomavirus (HPV) are important in the aetiology of cervical neoplasia is increasingly convincing[1]. We have demonstrated an association between the same HPV types (16 and 18) in anal squamous cell carcinoma in a series of cases.

In a preliminary series we have examined 50 patients, 20 normals and 30 with perianal warts. We have used a colposcope to look for subclinical dysplastic anal canal lesions equivalent to those described in the cervix. A 5 per cent acetic acid solution has been used to highlight these lesions. We have identified areas of anal intraepithelial neoplasia (AIN) in anoscopic biopsies from eight patients. DNA hybridization has detected HPV type 16 DNA in 2/8 of the AIN lesions. Subclinical anal wart virus infection was seen in addition to macroscopic warts in 24/30 wart patients.

These findings suggest that anal microendoscopy is a useful tool in the diagnosis of the subclinical anal manifestations of wart virus infection and we are continuing to assess its use in the diagnosis of dysplasia.

Biodegradable emboli increase the delivery of cytotoxic drug to hepatic tumours

D. Chang, S.A. Jenkins, D M. Nott, S. Grime and T. Cooke, *University Department of Surgery, Royal Liverpool Hospital, Liverpool, UK*

Degradable starch microspheres (DSM) combined with regional chemotherapy are being evaluated in patients. We have investigated whether DSM enhance delivery to tumour of both Adriamycin® (Farmitalia Carlo Erba, UK), which is actively taken up by hepatocytes, or a low molecular weight marker which is not.

In a rat model of hepatic metastases the optimum dose of DSM to minimize the passage of the relatively non-diffusable ^{99m}Tc-methylene diphosphonate (MDP) was established. ^{14}C-labelled Adriamycin alone and with DSM (half-life 20 min) was injected via the hepatic artery and its distribution determined after 90 min. In further studies MDP was injected with and without DSM and animals were killed immediately or after 90 min.

Adriamycin is preferentially retained in liver with a tumour to normal tissue ratio of 1 88±0·65 ng/mg 6 60±0 38 ng/mg ($P<0·001$ Mann–Whitney *U*) Concomitant injection with DSM increased tumour retention threefold to 7·87±0·7 ng/mg without affecting normal liver uptake (8 32±0 08 ng/mg) The tumour to liver ratio for MDP alone was 0 61±0 04.0·79±0·07 and DSM gave an immediate significant increase in this ratio to 26 03±2·81:8·67±0 81 ($P<0 001$) which was maintained at 90 min after complete degradation of DSM with a 14-fold retention in tumour (11 11±1 08:0 69±0 08, $P<0 001$)

DSM enhance hepatic tumour uptake of both a non-diffusable marker of similar molecular weight to common cytotoxic drugs, and a drug actively metabolized by hepatocytes, confirming its potential clinical benefit.

Changes in cell cycle kinetics during experimental colonic carcinogenesis

T. Cooke and J. Matthews, *Departments of Surgery, Royal Liverpool Hospital and Charing Cross Hospital, London, UK*

Crypt-cell production rate increases with the induction of colonic carcinogenesis[1] and we have investigated the mechanism of this.

Rats, administered the carcinogen azoxymethane or saline (as a control) subcutaneously for 12 weeks, were given vincristine 1 mg/kg intraperitoneally to arrest cells in metaphase at week 25, and were killed at 15-min intervals Metaphases were counted in the descending colon in 100 crypts per animal, expressed as a percentage of total crypt counts and plotted against time Entry into mitosis was calculated from the slope of the resulting regression line and cell cycle time derived as its reciprocal

There was a significant hyperplastic response in the carcinogenic rats compared with controls, increasing from 36·69±2 71 to 48 84±4·64 cells/crypt ($P<0·001$). The proliferation zone increased from 23 to 29 cells although the proportion of dividing cells (growth fraction) did not alter between controls (0·62) and carcinogenic groups (0 59) In the latter the rates of entry into mitosis decreased significantly from control values of 6·48 to 3·84 per cent of cells h^{-1} ($P<0 01$). Overall cell cycle time (T_c) increased from 30·86 h to 59·09 h; the T_c in stem cells was significantly reduced from control values of 112·0 h to 47·3 h ($P<0 01$) whereas, in contrast, the T_c in the proliferative compartment rose from 30·86 h to 66 4 h ($P<0 01$).

Absolute increases in the numbers of proliferating crypt cells, despite a slowing down of cell division, explains the previously observed elevation in crypt-cell production rate[1], advancing our understanding of the mechanism of colonic carcinoma development and may explain, in part, the failure of cytostatic therapy.

Host anti-tumour defences are not directly inhibited by lymphocyte circulation through the primary tumour

J.R T. Monson, W. Maxwell, P.W.N. Keeling, R.B. Stephens, F.B.V. Keane and W. A. Tanner, *Department of Surgery, Trinity College, Dublin, Ireland*

Some patients with gastrointestinal cancer have impaired cellular immune responses Colonic tumours produce excessive amounts of the immunosuppressive prostaglandin PGE$_2$. This study addresses the possible connection between these two findings by measuring lymphocyte function before and after *in vivo* circulation through colonic tumours

Blood was taken from both the arterial and venous systems of colonic tumours at the time of operation ($n=14$). Samples were assayed for lymphocyte transformation (using concanavalin A), T-cell subsets, interleukin 2 production, natural killer (NK) activity and lymphokine-activated killer (LAK) cell generation

	Lymphocyte transformation	IL-2 production	NK activity	LAK activity
Arterial	22441±3192	3 1±1 2	86 1±21 2	68 6±14 6
Venous	23022±3603	3·9±0·9	56 0±17·8	61 0±16·4

Lymphocyte transformation is measured in counts per minute; interleukin 2 production in units per millilitre; natural killer and lymphokine-activated killer activities in lytic units.

The results (mean±s e m.) revealed no difference between levels of lymphocyte function before and after the cells passed through the primary tumour. In addition there was no difference in the percentages of T-cell subsets between venous and arterial blood The results were unaffected by the Dukes' stage of the primary cancer

These data indicate that the immunosuppression exhibited by patients with gastrointestinal cancer may not be due to a locally exerted effect of the primary tumour and do not support regional perfusion of tumours with interleukin 2 However, further studies are now required in control subjects and those with benign colonic disease

Inhibition of colonic carcinogenesis by stearic acid in rats

S.B. Kelly, N.A. Habib, C B. Wood* and R C.N Williamson*, *Departments of Surgery, Bristol Royal Infirmary and *Royal Postgraduate Medical School, London, UK*

Malignant transformation of the cell reduces the stearic to oleic acid ratio in its cell membrane, thus decreasing membrane rigidity and increasing cell metabolism and proliferative activity Stearic acid has been shown to inhibit mammary carcinogenesis in rats Potential inhibition of colorectal carcinogenesis by stearic and oleic acid was tested in 72 male F344 rats which were allocated to one of four groups. (1) azoxymethane (AOM) alone, (2) AOM plus liquid paraffin, (3) AOM plus stearic acid and, (4) AOM plus oleic acid in liquid paraffin. AOM was administered by six weekly subcutaneous injections (15 mg kg^{-1} $week^{-1}$). Starting 1 week after the last AOM injection, the fatty acids were injected subcutaneously twice weekly at a dose of 25 mg in 0 5 ml liquid paraffin.

Group		Survival (weeks)	Small bowel tumours	Large bowel tumours
Control	($n=18$)	37 9±1·4*	1·1±0 2	1 5±0·2
Liquid paraffin	($n=18$)	36·3±1·2*	1 3±0·3	1·6±0 4
Oleic acid	($n=18$)	35·2±2·0	0 7±0·2	1 4±0 4
Stearic acid	($n=18$)	>45·3±1 2	0 3±0 3	1 5±0·7

All figures are means±s.e m.
Significance versus stearic acid *$P<0 001$

By week 44, all rats in the control and oleic acid groups were dead with tumour. By contrast, 11 of 18 rats in the stearic acid group are still alive and apparently tumour-free at 48 weeks There was no significant difference in survival between the control and the oleic acid groups In addition, the number of tumours in the small bowel and large bowel did not differ significantly between the groups. These results indicate that stearic acid prolongs survival in rats undergoing colonic carcinogenesis with azoxymethane.

Natural killer (NK) cell function: is the colon an immunosuppressive organ?

G. Jacob, L. Rawlinson, R C. Rees* and K. Rogers, *University Departments of Surgery and *Virology, Sheffield, UK*

The origin of reduced NK cell function in malignant disease is obscure. We have studied the effect of colonic vascular transit on NK cell cytotoxicity and the immunosuppressive activity of colonic venous plasma in patients with benign or malignant intra-abdominal disease

Heparinized blood (20 ml) was obtained from a peripheral vein, the aorta and colonic mesenteric veins in patients undergoing elective surgery for colonic carcinoma ($n=29$) or non-malignant disease ($n=13$) NK cells were harvested by a standard technique[1] and cytotoxicity assessed by a 4 h chromium-51 release assay using the K562 leukaemic cell line as the target With the same target the kinetics of NK cytotoxicity were studied by a single cell assay using plasma from the same patients[2] and lymphocytes from healthy donors.

Overall, colonic transit had no significant effect on NK cell cytotoxicity but in some patients enhancement ($n=6$) or suppression ($n=7$) was noted. However, colonic venous plasma proved suppressive to NK-mediated cytolysis, both from patients with benign and malignant disease

Table 1 *Host NK cell cytotoxicity (%) to K562 leukaemic cell line*

	Arterial	Tumour venous	Colon venous	Peripheral venous
Carcinoma ($n=29$)	28±15	26±14	25±15	23±12
Benign ($n=13$)	26±17	—	29±19	26±20

Table 2 *Immunosuppression by host plasma of donor NK cell cytotoxicity (%) to K562 leukaemic cell line*

	Autologous	Arterial	Tumour venous	Colon venous	Peripheral venous
Carcinoma ($n=29$)	36±13	29±11	21±11*	21±11*	30±09
Benign ($n=13$)	34±06	27±10	—	20±08*	27±10

All values as mean±1 s d *$P>0\cdot001$ t-test

In conclusion colonic vascular transit has no consistent effect on NK function but colonic venous plasma contains an unidentified, soluble immunosuppressant This factor acts at a post-recognition phase of the cytotoxic process and further studies are required for its characterization.

Endotoxaemia in experimental obstructive jaundice and following its relief by internal and external biliary drainage

T Diamond, R.L E. Thompson, E McGlone and B J. Rowlands, *Department of Surgery, The Queen's University of Belfast, UK*

Endotoxaemia has been demonstrated in experimental models and patients with obstructive jaundice and is associated with postoperative renal failure, sepsis and haemorrhagic gastritis. It is postulated that absence of intraluminal bile salts predisposes to portal absorption of gut endotoxin and that endotoxaemia is reversed by oral bile salt therapy, or internal biliary drainage and return of bile salts to the gut, but not by external biliary drainage We believe that relief of biliary obstruction and restoration of normal hepatocyte and Kupffer cell function is a more important contributing factor to the reversal of endotoxaemia than restoration of gastrointestinal (GI) bile flow. The aim of this study was to determine the relative roles of biliary obstruction and GI bile flow in the development and reversal of endotoxaemia.

Portal and systemic endotoxin concentrations were measured using a quantitative Limulus assay in control rats, 2 weeks after bile duct ligation (BDL) and 2 weeks later after relief of biliary obstruction by internal drainage (ID. choledochoduodenostomy) or sterile external drainage (ED choledochovesical fistula[1])

	Portal endotoxin mean±s e m. (pg/ml)	Systemic endotoxin mean±s e m (pg/ml)
Controls ($n=10$)	224±85	240±77
BDL 2 wks ($n=15$)	1304±129*	918±110*
BDL 2 wks+ID 2 wks ($n=8$)	442±87	328±67
BDL 2 wks+ED 2 wks ($n=8$)	383±165	376±94

Significance *versus* controls· * $P<0\cdot005$, bilirubin was elevated in BDL (201±12 μmol/litre) compared with controls, ID and ED (Mann–Whitney U test)

It was concluded that significant portal and systemic endotoxaemia occurred in BDL compared with controls Relief of biliary obstruction by both internal and external drainage reversed portal and systemic endotoxaemia This confirmed that relief of biliary obstruction is a more important factor than restoration of intraluminal GI bile flow in the reversal of endoxaemia

Enhancement of mucosal cell migration in experimental gastric stress ulceration.

R. Stuart, T.F. Gorey, R. Flynn, S. McBennett, E. Kay, P. Byrne and T P.J Hennessy, *Trinity College Dublin Department of Surgery, St. James's Hospital, Dublin, Ireland*

Mucosal ulceration is the result of an imbalance between ulcerogenic and protective elements, one of which is the ability of mucosal cells to replicate and restore surface continuity To study this restitution process nuclear DNA was radiolabelled with tritiated thymidine, and after autoradiography a labelling index was calculated from the ratio of labelled to total cells, and their migration position was measured along the length of the gastric gland. Two groups each of 24 Wistar rats (mean weight 85·2±4·3 g) were studied immediately and 48 h after cold restraint stress which caused histologically proved mucosal ulcers Thymidine uptake and cell position, indicating mitotic and migration rates, were assessed in 20 glands per animal for a representative 100 labelled cells in each of four groups controls ($n=9$), stress, untreated ($n=5$); stress, with cimetidine prophylaxis ($n=5$), and stress, with allopurinol prophylaxis ($n=5$) The table shows total labelling and cell position indices immediately and (in parentheses) 48 h after stress

Cell position	Normals	Untreated stress	Cimetidine	Allopurinol
Surface	6·13 (24·69)	6·33 (10·3)	9·29 (25·41)*	14·00* (12·42)
Proliferative zone	16·81 (16·35)	12·58† (9·89)	16·19 (12·88)	15·43 (10·73)
Percentage of total labelled	8·43 (13·09)	5·31 (7·17)	7·03* (10·44)	7·84* (6·40)

* $P<0\cdot001$ *versus* untreated stress; † $P<0\cdot001$ *versus* normals, unpaired Student's t test

Immediately after stress, total labelling indices show a depression of cell division while cell position index shows enhanced surface migration, allopurinol was most effective in promoting early proliferation and migration After 48 h, migration is greatest with cimetidine while lower indices in the allopurinol group may represent intraluminal shedding of already migrated cells.

Endothelial cell seeding: the influence of different luminal coatings on initial cell attachment to polytetrafluorethylene vascular grafts

J.S. Budd, R.F.L James and P.R.F. Bell, *Department of Surgery, University of Leicester, Leicester, UK*

The creation of a biocompatible, intravascular prosthesis may ultimately require a surface covered with endothelial cells that are actively antithrombogenic. In humans, however, the number of cells available for seeding is small, and in order to achieve any benefit from endothelial cell seeding the vast majority of harvested cells need to attach in a relatively short time period We have examined the role of different surface coatings in enhancing endothelial cell attachment to polytetrafluoroethylene (PTFE) vascular grafts.

Human umbilical vein endothelial cells were harvested by collagenase digestion and labelled with indium-111 oxime. The cells were then inoculated on to small segments of PTFE graft material which was either uncoated, or coated with gelatin, collagen, or fibronectin. At 30, 60 and 120 min the surfaces were washed and the radioactivity in the washings and on the graft segment was measured. Cell attachment was measured as a percentage of the initial inoculum

	Control	Gelatin	Collagen	Fibronectin
30 min	7·46±0 87	9·29±0·91*	37 00±2·57*	53·16±3 21*†
60 min	10·41±1·78	22·48±3 46*	40 76±2·38*	59 78±1 84*†
120 min	14·86±2 34	31·16±5 46*	46·22±2 97*	60 81±3 00*‡

Data are mean±s.e.m.; * $P<0\ 01$ *versus* control; † $P<0\ 01$, ‡ $P<0\ 05$ collagen *versus* fibronectin

In conclusion, pretreatment of PTFE vascular grafts with gelatin, collagen or fibronectin significantly improves the initial attachment of seeded endothelial cells Fibronectin appears to be the most effective substance in this respect

Digital or manometric assessment of anal sphincter function

R.I. Hallan and N.S. Williams, *The Surgical Unit, The London Hospital, London, UK*

Anal canal manometry is not readily available and most surgeons make management decisions based solely upon the subjective assessment of sphincter strength as felt by their right index finger. To discover whether this is an adequate measurement of sphincter function, scores (0–10) were given for the digital impression of basal and squeeze sphincter strength by one surgeon in 22 incontinent (I) and 44 continent (C) patients (22 control subjects and 22 severely constipated patients). Maximum basal (MBP) and maximum squeeze (MSP) anal canal pressures were then determined by a standard manometric station-pullthrough technique

There was a good correlation between MBP and the basal score ($r=0\ 52$, Spearman's rank correlation coefficient, $P<0{\cdot}001$) There was an even better correlation between MSP and the squeeze score ($r=0{\cdot}72$; $P<0\ 001$) MBP in incontinent patients (median 39, interquartile range 25–59 cmH_2O) was significantly lower than in the continent (72, 54–95 cmH_2O; $P<0\ 001$, Mann–Whitney U test), and this difference was detected by the basal scores (5, 3–6 I; 8, 7–9 C, $P<0{\cdot}001$). MSP in incontinent patients (43, 19–65 cmH_2O) was significantly lower than in the continent (70, 50–105 cmH_2O; $P<0\ 001$) and again this difference was detected by the squeeze score (3, 1–6 I, 8, 7–9 C; $P<0\ 001$)

It appears that assessment of anal sphincter function by the index finger of an experienced surgeon is equally as good as anal canal manometry, and is therefore adequate for most clinical purposes. Manometry nevertheless has its place in the investigation of coloproctological disorders, particularly in the setting of anorectophysiological research where objective data are required

Dietary lipids and breast carcinogenesis

G.A. Pritchard, D.L. Jones and R.E. Mansel, *Department of Surgery, University Hospital of Wales, Cardiff, UK*

Excess dietary fat is identified as a risk factor for development of breast cancer Polyunsaturated essential fatty acids (EFA) may, however, have an antitumour effect[1].

We have studied the effect of dietary fat on the growth of human breast adenocarcinoma MCF7 xenografts in athymic mice Normal chow was supplemented with corn oil or n-6 and n-3 series EFAs present in natural preparations of primrose oil and fish oil. Tumours were excised after 5 weeks and tumour mass measured.

Diet	n	Tumour mass (mg)		2P value (Mann–Whitney U)
		Median	Range	
Control	14	68	32–125	—
5% corn oil	11	68	30–152	0·84 n s
10% corn oil	14	73	28–250	0 69 n s.
20% corn oil	17	142	83–198	0 01
5% primrose oil	12	12	6–31	0 002
10% primrose oil	12	13	5–44	0 01
5% fish oil	13	45	32–78	0 31 n.s.
10% fish oil	11	15	7–34	0 004

The table shows that 5 and 10 per cent corn oil had no effect, while the high-fat diet of 20 per cent corn oil enhanced tumour growth. This is the first report of human breast tissue being responsive to fat and corroborates earlier epidemiological surveys which implied a nutritional risk factor[2] Primrose oil and fish oil supplements significantly inhibited tumour growth. Hence, nutritional intervention with EFAs may have a role as a preventive or therapeutic measure to complement existing therapies

A prospective randomized trial to compare sutures and staples in the construction of colorectal anastomoses

A.M. Akyol, J.R. McGregor*, D.J. Galloway, B.A. Sugden*, A Munro†, G. Bell‡, W.D. George, *University Department of Surgery, Western Infirmary, Glasgow, *Crosshouse Hospital, Kilmarnock, †Raigmore Hospital, Inverness, ‡Inverclyde Royal Infirmary, Greenock, UK*

Despite the widespread use of both suturing and stapling techniques, few studies have scientifically compared them. We report a prospective randomized study of 174 colorectal anastomoses designed to compare sutured (single layer, interrupted polyamide, group A, $n=91$) with stapled cases (EEA® circular stapler, US Surgical Corporation and Autosuture UK, Ascot UK; group B, $n=83$). The mean age was 65·6 years in group A and 67·3 years in group B while the proportion with colorectal cancer was 74 per cent and 72 per cent respectively Numerous pre- and perioperative data were collected including anastomosis and total operating times. Postoperatively a modified sepsis score was monitored and an assessment of anastomotic integrity made, including contrast radiology in 85 per cent of cases.

The anastomosis and operating times along with leak rates are shown in the *Table* There were six perioperative deaths. None of the five in group A resulted from anastomotic complications, unlike the death in group B

We conclude that the use of circular staplers for colorectal anastomoses significantly reduces anastomosis and operating times. Otherwise the results were comparable to those achieved with conventional suturing

	Group A	Group B	P
Anastomosis time min	33 0	21 8	<0 001*
(s e.m.)	(+1·48)	(+1·3*)	
Operating time: min	142 1	127·2	<0 05*
(s.e.m)	(+4 89)	(+4 77)	
Radiological leaks (%)	10 (11%)	4 (4 8%)	0 09†
Clinical leaks (%)	5 (5·5%)	6 (7·2%)	0 64†

* Student's t test, 172 d f, † χ^2 analysis

An evaluation of the safety of piezoelectric lithotripsy in a guinea-pig gallbladder model

A. Darzi, I.M. Reid, E. Kay, J.R.T. Monson, W.A. Tanner and F.B.V. Keane, *Department of Surgery, The Meath and Adelaide Hospitals, Dublin, Ireland*

Controversy surrounds the capacity of extracorporeal shock-wave lithotripsy to cause soft-tissue injury. To address this question, we subjected four groups of guinea-pigs to shock waves. The animals were subjected to different dosages and were killed at different intervals to determine the immediate or delayed effects of increasing the number of shock waves. Macroscopic and microscopic injury to the gallbladder and the neighbouring structures was quantified. Macroscopic changes included haematomata of the gallbladder or neighbouring organs, while the microscopic changes were intramural haemorrhage, eosinophilic infiltrate, small vessel damage and mucosal disruption. Animals were designated as injured or non-injured based on the presence or absence of the above features.

Group	Shock waves	Time of killing	No. of animals injured	%
Group 1	6000	24 h	2	8
Group 2	24 000	24 h	3	33
Group 3a	48 000	24 h	12	100
Group 3b	48 000	2 weeks	2	25
Group 3c	48 000	1 month	0	0
Group 4	6 × 6000 over 6/52	1 week after the last treatment	1	12

The percentage injury was significantly higher in the high-dose lithotripsy (group 3a *versus* group 1, $P<0·001$) and, although these injuries were reversible (group 3b and 3c), it seems that treatment with 6000 piezoelectric shock waves is associated with the least injury and could be administered safely at weekly intervals to a total of 36 000 shock waves.

Prophylactic combination chemotherapy is more effective in preventing peritoneal hydatid cyst development than either albendazole or praziquantel alone following spillage of live protoscolices of Echinococcus granulosus

D.H. Taylor and D.L. Morris, *Department of Surgery, University Hospital, Nottingham, UK*

Recurrence is an important problem after an operation for hydatid disease in man, occurring in as many as 10 per cent of patients.

Thirty-nine gerbils received an intraperitoneal injection of approximately 4000 protoscolices of *Echinococcus granulosus* to simulate surgical spillage. Nine of these gerbils acted as untreated infected controls. The remaining 30 received chemotherapy by daily gavage for 1 month starting on the day of infection: 10 received albendazole (50 mg kg^{-1} day^{-1}), 10 received praziquantel (500 mg kg^{-1} day^{-1}), and 10 received a combination of the two drugs. Eight months after inoculation the gerbils were killed. The number of cysts in each gerbil was recorded.

All chemotherapy significantly reduced ($P<0·01$) cyst numbers. With albendazole, the cysts recorded totalled 22·6 ± 10 per gerbil, with praziquantel 5·9 ± 1·09 and with combination chemotherapy 0·8 ± 0·29, these compared with control figures of 67·6 ± 12·8 per gerbil. Combination chemotherapy was significantly more effective than either of the two drugs given alone ($P<0·001$).

A prospective randomized controlled clinical trial comparing somatostatin and injection sclerotherapy in the control of acute variceal haemorrhage: a preliminary report

S.A. Jenkins, S. Ellenbogen, J.N. Baxter, I. Gilmore, A. Morris and R. Shields, *University Departments of Surgery and Medicine, Royal Liverpool Hospital, Liverpool, UK*

Recent studies have suggested that somatostatin (SRIF) may be of value in the control of bleeding from oesophageal varices. However, in view of the efficacy of injection sclerotherapy in controlling variceal bleeding, it has been suggested that this treatment should be the 'gold standard' against which new therapies are evaluated. Therefore, the aim of this study was to compare the efficacy of SRIF with emergency injection sclerotherapy in the control of acute variceal haemorrhage.

Forty-three consecutive patients admitted with endoscopically proved, severe, bleeding oesophageal varices were randomized to either emergency injection sclerotherapy or SRIF (bolus dose of 250 μg followed by a continuous infusion of 250 μg h^{-1} for 5 days). The aetiology of the accompanying portal hypertension was similar in the two groups as was the distribution of the patients among the categories of Child's classification.

Twenty-two patients received SRIF and 21 injection sclerotherapy. The initial variceal haemorrhage was controlled in all 22 patients receiving SRIF but three bled during the 5-day trial period. Overall control of bleeding was achieved in 19 of the 21 patients randomized to injection sclerotherapy. There was no significant difference ($P=0·52$, Fisher's exact test) between the two forms of treatment.

The initial results of this trial suggest that SRIF is as effective as injection sclerotherapy in controlling acute variceal haemorrhage.

Evaluation of the role of endoscopic sphincterotomy in the treatment of sphincter of Oddi dysfunction

G.M. Fullarton and W.R. Murray, *University Department of Surgery, Western Infirmary, Glasgow, UK*

Postcholecystectomy pain due to sphincter of Oddi dysfunction remains a difficult condition to treat although endoscopic sphincterotomy has been recommended for those patients with confirmed sphincter of Oddi motor abnormalities. We have studied patients with sphincter dysfunction to evaluate the effects of sphincterotomy on their clinical response and on previously reported scintigraphic findings to determine the efficacy of this treatment.

Nine postcholecystectomy patients (two men, seven women, median age 59 years) with clinical and manometric evidence of sphincter dysfunction underwent sphincterotomy for persisting biliary-type pain. Each patient had scintigraphy before and 8 weeks after operation. The patients' clinical response was independently assessed at 3-monthly intervals following sphincterotomy. Scintigraphic analysis demonstrated that the time in minutes to reach maximum counts was significantly reduced from 26·1 ± 1·9 (mean ± s.e.m.) before sphincterotomy to 17·9 ± 1·5 after it ($P<0·01$). Seven out of 9 (78 per cent) patients with dysfunction had a significant improvement in their symptoms after a mean follow-up period of 12 months (range 6–19) although only 6 out of 9 were totally free of pain. These results suggest that endoscopic sphincterotomy in manometrically confirmed dysfunction of the sphincter of Oddi improves bile drainage as measured by quantitative cholescintigraphy and produces at least short-term relief of symptoms.

Does APACHE-II help to predict severity of acute pancreatitis? A prospective comparison with other prognostic systems

M. Larvin and M.J. McMahon, *University Department of Surgery, The General Infirmary, Leeds, UK*

Death from acute pancreatitis results from fulminant major-organ failure early in the attack, or more commonly from late septic complications of pancreatic necrosis. Prediction of organ failure and necrosis is important for evaluation of medical and surgical treatments, and as an aid to management. Existing multiple criteria systems (Ranson, Imrie) measure initial severity, and cannot predict pancreatic necrosis. Acute Physiology/Chronic Health Enquiry (APACHE-II) scores[1] allow initial assessment and sequential monitoring of major-organ failure and sepsis.

A prospective evaluation of APACHE-II scores was undertaken in 290 attacks of acute pancreatitis. By predefined criteria, complications were classified as early major-organ failure (within first week) ($n=24$) and pancreatic necrosis, proved at autopsy or laparotomy ($n=15$). Data were collected to calculate Ranson, Imrie and daily APACHE-II scores.

		Complications			
		Multi-organ failure		Pancreatic necrosis	
Time (h)	System and cut-off level	Sensitivity	PPV (%)	Sensitivity	PPV (%)
0	APACHE-II > 10	83·3	32·3	80·0	19·4
24	APACHE-II > 9	87·5	33·3	86·7	20·6
48	APACHE-II > 8	91·7	35·5	86·7	21·0
48	Ranson > 2	83·3	16·7	80·0	10·0
48	Imrie > 2	66·7	26·2	66·7	16·4
72	APACHE-II > 8	91·7	36·2	86·7	21·3
96	APACHE-II > 8	91·7	39·3	93·3	24·6

PPV, positive predictive value.

Admission APACHE-II scores provided similar accuracy to Ranson and Imrie scores at 48 h for identifying severe attacks. Ranson and Imrie scores proved poor at predicting necrosis compared with APACHE-II scores, which could detect necrosis and necrosis plus organ failure with increasing accuracy after 3 days. The APACHE-II system has the potential to identify severe attacks, providing more rapid stratification of patients for entry into clinical trials, and sequential APACHE-II scores may give early warning to clinicians of pancreatic necrosis.

1 Knaus WA, Draper EA, Wagner DP *et al* APACHE-II a severity of disease classification. *Crit Care Med* 1985; **13** 818–29

Oxygen free radical-dependent and radical-independent release of gut peptides in intestinal ischaemia

L. Meleagros, R.A. Spokes, J. Domin, M.A. Ghatei and S R. Bloom (introduced by R.C.N. Williamson), *Department of Medicine, Royal Postgraduate Medical School, Hammersmith Hospital, London, UK*

Ischaemia and reperfusion causes intestinal injury by at least two, possibly linked, mechanisms: oxygen free radical (oxy-radical) generation and activation of the enzyme phospholipase A_2 (PLA_2) By inhibition of oxy-radical generation with allopurinol and of PLA_2 with quinacrine, an investigation was made of their role in the release of the gut peptides vasoactive intestinal polypeptide (VIP), β-calcitonin gene-related peptide (β-CGRP), peptide YY (PYY); somatostatin (Som) and enteroglucagon (EG) from reperfused ischaemic intestine Three groups (B, C, D, $n=6$ per group) of anaesthetized male Wistar rats were subjected to superior mesenteric artery (SMA) occlusion for 20 min followed by reperfusion for 20 min. Animals in group B were untreated. Group C received allopurinol 50 mg kg^{-1} day^{-1} orally for 3 days and 50 mg kg^{-1} intravenously; and group D received quinacrine 10 mg kg^{-1} intravenously before SMA occlusion. Control animals ($n=6$, group A) had sham SMA occlusions Arterial blood samples were taken after reperfusion and plasma peptides were measured with specific radioimmunoassays. Results (mean ± s.e.m. fmol/ml), analysed by ANOVA, are shown below.

Group	VIP	β-CGRP	PYY	Som	EG
A	3±0·6	15±3	9±2	21±7	38±1
B	28±3***	37±7*	37±6***	61±8**	135±11***
C	32±6***	18±4†	36±6***	30±6‡	65±10*†
D	30±4***	21±4	37±8***	38±8	103±22**

* $P<0{\cdot}05$, ** $P<0{\cdot}005$, *** $P<0{\cdot}001$ (*versus* control); † $P<0{\cdot}05$, ‡ $P<0{\cdot}01$ (*versus* no treatment)

These findings demonstrate that injury mediated by the oxy-radical causes the release of β-CGRP, Som and EG but not VIP and PYY. PLA_2 activation is not a major mechanism of peptide release Therefore, measurement of plasma levels of gut peptides can differentiate between those that are dependent or independent of the oxy-radical and PLA_2-induced intestinal ischaemia/reperfusion injury

In vivo comparison of proglumide and CR-1409 inhibition of cholecystokinin-induced changes in the biliary tract of the guinea-pig

G.J. Poston and J.C. Thompson, *Department of Surgery, UTMB, Galveston, Texas, USA*

The purpose of this study was to compare the effects of two cholecystokinin (CCK) antagonists, proglumide and CR-1409, on CCK-induced changes in intrabiliary pressure *in vivo* We have substantially modified the constant infusion biliary manometry model, successfully used in large animals, to measure gallbladder contractility in guinea-pigs A silicone manometry catheter was placed in the gallbladder fundus of an anaesthetized guinea-pig, and the biliary tree was constantly infused at 0·1 ml/min with saline The intraluminal pressure of the system was continuously recorded The model was used to demonstrate a dose-response curve to bolus administration of exogenous CCK (from 0·01 to 1·0 nmol/kg), and also to study the actions of proglumide, a specific antagonist to gastrin and cholecystokinin (CCK), and CR-1409, a newer CCK antagonist, on CCK-induced contraction of the guinea-pig gallbladder *in vivo*. Proglumide at a dose of 5 mmol/kg completely abolished increases in intrabiliary pressure caused by CCK (0·5 nmol/kg), whereas this effect was achieved by only 5 μmol/kg of CR-1409. In both cases there was full recovery from CCK antagonism within 1 h CR-1409 is thus 1000 times more potent than proglumide against CCK-induced changes in intrabiliary pressure *in vivo*, and appears to be a useful pharmacological reagent to study CCK-mediated components of physiological contraction of the gallbladder

The effects of vasoactive drugs on the collateral circulation of rats with portal hypertension

S.A Jenkins, J. Yates, D.M. Nott, S. Ellenbogen, T. Cooke and R. Shields, *University Department of Surgery, Royal Liverpool Hospital, Liverpool, UK*

It is generally assumed that control of variceal bleeding by vasoactive drugs results from a reduction in collateral bloodflow secondary to splanchnic vasoconstriction and a reduction in portal pressure, a hypothesis which has never been validated directly. The aim of this study was to investigate the effects of vasoactive drugs on collateral bloodflow and portal pressure simultaneously in rats with portal hypertension

Rats with portal hypertension (partial portal vein ligation) received intravenous bolus doses of 2 μg somatostatin (SRIF), 2 μg SMS 201-995, 0·4 i.u. vasopressin or the same volume of isotonic saline over 30 s Arterial blood pressure and portal pressure (PP) were recorded continuously whilst collateral bloodflow was measured before and after the administration of drugs or saline, by consecutive intrasplenic injection of a non-diffusable marker, ^{99}Tc-methylene diphosphonate and ^{99m}Tc-albumin microspheres

Vasopressin elicited the greatest reduction in portal pressure (from 13·00±0·71 to 6·88±0·75 mmHg; $P<0{\cdot}001$ Student's paired *t* test) but had no significant effect on collateral bloodflow. Both SRIF and SMS 201-995 also significantly reduced portal pressure but to a lesser degree than vasopressin However, both SRIF and SMS 201-995 significantly reduced collateral bloodflow (SRIF from 26·83±4·42 to 11·33±1·79 per cent, SMS 201-995, from 36·25±6·93 to 20·88±6·4 per cent, $P<0{\cdot}001$).

These results indicate that SRIF and SMS 201-995, although having a less marked effect than vasopressin on portal pressure, produce a much greater effect on collateral bloodflow which may partly explain their greater efficacy in controlling acute variceal bleeding.

Converted striated muscle neosphincter: a canine model

R.I. Hallan, N.S. Williams, M.A. Pilot, M.F. Grahn, T H. Koeze* and E.S. Watkins*, *Surgical and *Neurosurgical Units, The London Hospital, London, UK*

The outcome of the gracilis sling procedure for faecal incontinence is often unsatisfactory as the sphincter is adynamic. Electrical stimulation of the muscle might result in adequate and appropriate sphincter contraction To investigate this an electrically controlled sphincter model was created in six dogs The sartorius muscle was mobilized on its neurovascular pedicle into the abdominal cavity to form a sphincter around a Thiry–Vella loop. Electrodes connected to an external stimulator were sutured close to the nerve supplying the muscle The sphincter was able to reduce or stop the flow of water through the Thiry–Vella loop, but only for a short period of time due to muscle fatigue. To overcome this, chronic low-frequency stimulation (CLFS) from an implanted stimulator was used to convert the fatiguable, fast-twitch muscle to a fatigue-resistant, slow-twitch muscle. After 6 weeks there was a significant change in the tetanic fusion frequency, the time from stimulus to peak tension recorded by a strain gauge, and muscle enzyme activities The successful conversion resulted in a significant prolongation of sphincter competence

	Fusion frequency	Time from stimulus to peak tension	Time sphincter remains competent
Before CLFS	20 (2) Hz	63 (7) ms	1·5 (0·9) min
After CLFS	12 (2) Hz	187 (11) ms	6·3 (2·3) min
Paired *t* test	$P=0{\cdot}01$	$P=0{\cdot}002$	$P<0{\cdot}05$

Data are all means (s.e.m.)

The electrically stimulated sartorius neosphincter functions well in the dog This technique should improve the gracilis sling procedure when used to treat faecal incontinence and is currently being evaluated in humans

Home assessment of anorectal motility and external sphincter EMG in idiopathic faecal incontinence

D. Kumar, D Waldron and N S. Williams, *Surgical and Gastrointestinal Science Research Units, London Hospital Medical College, London, UK*

Patients with idiopathic faecal incontinence are conventionally assessed in a laboratory setting for a short period of time These studies have led to the belief that impairment of external anal sphincter is the main aetiological factor

To evaluate the role of internal and external sphincters in idiopathic faecal incontinence, we studied six subjects with incontinence and 14 healthy controls for a mean duration of 21 0 and 20 3 h per subject respectively. Pressure was recorded by a two-channel Gaeltec probe with sensors positioned in the rectum and mid-anal canal respectively. External sphincter EMG activity was recorded by surface electrodes applied 0 5 cm from the anal verge All subjects ate normal meals and slept at home Patients with faecal incontinence showed more (*P* <0 01) episodes of anal relaxation the mean ± s.e m. was 11 6 ± 1 8 h^{-1} *versus* healthy controls 7 4 ± 2 0 h^{-1} Their duration of anal relaxation was significantly longer than in healthy controls (48 ± 3·1 s *versus* 28 4 ± 3 9 s, *P* <0 001) External sphincter EMG activity in the two groups was not statistically different: incontinent patients had 14·2 ± 2·8 action potentials per 10 min while controls had 12 8 ± 3·2. Our data show that anal relaxation occurs more frequently and for a prolonged period of time in patients with idiopathic faecal incontinence; the external anal sphincter does not appear to be affected We conclude that the incontinence is the result of internal anal sphincter dysfunction rather than the external sphincter as is more generally believed.

Does anal sphincter function improve following restorative proctocolectomy?

W.A Kmiot, M. Pinho, K. Yoshioka and M R.B. Keighley, *The General Hospital, Birmingham, UK*

In order to determine the influence of time on anal sphincter pressures following restorative proctocolectomy, 10 patients had anal pressures measured preoperatively and at 3, 6 and 12 months after operation. A closed rigid 5-mm diameter catheter with a 1-cm water-filled balloon was used to measure anal pressure at 1-cm intervals along the anal canal A further 12 patients had similar measurements 18 and 24 months after operation. The median age was 28 years (range 18–44 years) All ileo-anal anastomoses had been hand sutured and all mucosectomies performed from above; pouch design was J ($n=12$) or W ($n=10$). Maximum resting anal pressures were lower at 3 months (median 80 (range 50–100), *P* <0 03, Wilcoxon matched pairs test), 6 months (90 (50–150); *P* <0 01) and 12 months (100 (70–135)) postoperatively than before operation (110(70–160)) Furthermore, the resting pressure at 24 months (105 (50–160)) was higher than at 18 months (100(50–150), *P* <0 05). Maximum squeeze anal pressures were lower at 3 months (185 (150–230), *P* <0 03) and 6 months (200 (150–300), *P* <0 01) postoperatively than before operation (250 (190–300)) However, this difference was not significant at 12, 18 and 24 months Patients with preoperative resting anal pressures lower than the median of 110 cmH_2O had a greater number of soiling episodes postoperatively than the remainder (3·5/24 h *versus* 1 2/24h)

Resting anal pressure improves after restorative proctocolectomy and probably accounts for decreasing soiling episodes with increasing time after operation

Anal continence depends on sphincter recruitment by stress rather than absolute sphincter strength

N.R Womack, J F.B. Morrison* and N.S Williams, *Surgical Unit, The London Hospital, London and *The Department of Physiology, The University of Leeds, Leeds, UK*

Neurogenic weakness of the external anal sphincter is implicated in the aetiology of idiopathic faecal incontinence yet only some patients with such weakness develop incontinence To investigate why this is so EMG activity of the sphincter was recorded in three groups, each comprising 25 women and five men. control subjects (mean age 59 ± s.e.m 2 7), continent patients (aged 51 ± 2 8) and incontinent patients (aged 65 ± 1 9, *P* <0 001 compared with continent patients); the patients had a similar degree of sphincter weakness on manometric and fibre-density testing. Recordings were made whilst continence was threatened in two ways first, rectal distension was simulated by balloon distension to maximal tolerable volume; and secondly, intra-abdominal pressure was raised by a series of forced expirations.

Sphincter behaviour in the study groups was significantly different in both situations. Rectal distension to maximal tolerable volume produced sphincter inhibition to levels of activity below those present at rest in 44 per cent of controls, 28 per cent continent patients, and 72 per cent of incontinent patients (*P* <0 01 compared with continent) The rise in intra-abdominal pressure necessary to cause sphincter recruitment was raised in both study groups, with the impairment significantly greater in the incontinent patients then in the continent patients (controls 0 8 ± 0·4 cmH_2O, continent 3 3 ± 0 7, *P* <0 002 compared with controls, incontinent 7 0 ± 1 1, *P* <0 001 compared with controls, *P* <0 002 compared with continent).

These results imply that in the clinical situation the manner in which the external anal sphincter responds when continence is threatened may be more important than sphincter strength *per se* in determining whether continence is maintained

Five-year follow-up of changes in pelvic floor innervation after childbirth

S J. Snooks, M M. Henry and M Swash, *St Bartholomew's and St. Mark's Hospitals, London, UK*

Fourteen multipara of mean age 31 5 (range 29–34 years) were studied employing the techniques of single-fibre electromyography (SFEMG), transrectal pudendal nerve stimulation, anorectal manometry and assessment of perineal descent Each woman was studied at 3 months before delivery, and at 48 h, 2 months and 5 years after vaginal delivery These results show that the pudendal nerve terminal motor latency (PNTML) and SFEMG fibre density of the external anal sphincter (EAS) muscle remained significantly increased 5 years after the initial monitored vaginal delivery compared with nulliparous control subjects (*P* <0 01) Perineal descent on straining no longer occurred in 11 women; however, anal canal pressures on voluntary contraction remained significantly low.

Seven women had increased fibre density in the sphincter muscle, five of whom had increased PNTML A further three women had increased PNTML alone, but latency was unilaterally unrecordable in three These multipara therefore had evidence of progressive denervation associated with continuing mechanical weakness of the external sphincter muscle despite, in 11 women, a complete absence of perineal descent.

Five women with increased PNTML and fibre density had stress incontinence of urine, three of whom also had incontinence of flatus These results are consistent with progressive damage to the innervation of the external anal sphincter muscle in multipara after vaginal delivery.

Time	PNTML (ms) Right	PNTML (ms) Left	FD of EAS	Voluntary contraction (cmH_2O)	Perineal descent (cm)
Antenatal	—	—	1 42 ± 0 21	73 5 ± 31 1	0 82 ± 0 57
Postnatal					
48 h	2 23 ± 0 29*	2 37 ± 0 67*	—	47 3 ± 13 0*	−1 55 ± 0 50*
2 months	1 97 ± 0 12	1 89 ± 0 22	1 59 ± 0 25*	50 0 ± 30 0*	−1·02 ± 0 48*
5 years	2 25 ± 0 18*	2 3 ± 0 5*	1·82 ± 0 47*	50 0 ± 29 9*	+0 87 ± 0 66
Controls	1 90 ± 0 20	2 0 ± 0 20	1 30 ± 0 16	104 7 ± 50 5	+0 08 ± 0 70

* *P* <0 01 significant difference from controls (Wilcoxon's rank sum test)

Does psychological and pain stress affect anorectal motility and external sphincter activity in humans?

D. Kumar, D Waldron, D L. Wingate and N S. Williams, *Surgical and Gastrointestinal Science Research Units, London Hospital Medical College, London, UK*

To evaluate the effect of psychological and pain stress on the human anorectum and external sphincter, we studied six healthy subjects (three men and three women, age range 20–55 years) Anorectal motility was measured using a Gaeltec probe with sensors located in the mid-anal canal and rectum External sphincter EMG activity was recorded by surface electrodes Psychological stress was applied by requiring the subject to play a competitive video game for 30 min, and pain stress applied by immersing the hand in ice-cold water for 30 min, these two forms of stress were separated by a rest period of 30 min. Anorectal motility and external sphincter EMG for the two stress periods were compared with those under unstressed conditions but in the same posture. There was a rise of 10 ± 3·8 mmHg in the anal canal pressures during the two stress periods Intermittent phasic contractions, seen in the rectum and anal canal, were virtually abolished in all subjects during both stress periods Normal external sphincter EMG activity (11 ± 1·9 action potentials per 30 min) was reduced to 4 ± 1·3 under stress (*P* <0 01) Our data show that both psychological and pain stress inhibit rectal motility and external sphincter activity but produce a sustained tonic rise in anal canal pressure, reflecting an increased tone in the internal anal sphincter.

'Total pelvic floor' repair is superior to conventional postanal repair for faecal incontinence

M. Pinho, K. Yoshioka and M.R.B. Keighley, *The General Hospital, Birmingham, UK*

Postanal repair is often associated with poor results Since postanal repair does not correct the deficient anorectal angle and as there is preoperative evidence of anterior pelvic floor weakness in many patients' with incontinence, we have added an anterior levatorplasty and anterior external anal sphincter plication to conventional postanal repair. 'total pelvic floor repair'

Fifteen patients have been prospectively studied before and after total pelvic floor repair using pre- and postoperative manometry and videoproctography. Results have been compared with 15 patients having conventional postanal repair. At a mean follow-up of 6·2 months after total pelvic floor repair, complete continence was recorded in eight (53 per cent), an improvement in five (33 per cent) and no difference in two (13 per cent) By contrast, after postanal repair at the same period of follow-up, complete continence was recorded in only five (33 per cent), improvement in four (27 per cent) and six (40 per cent) were no better. A significant decrease in pelvic floor descent and a lower rest position were found after total pelvic floor repair but there was no difference after postanal repair. Manometric studies found no significant difference after repair in either group Anterior levatorplasty with anterior external sphincter plication was performed in eight postanal repair failures, with improvement of continence recorded in seven.

Prolonged follow-up, as well as an ongoing prospective randomized study, is expected to define the role of total pelvic floor repair in the treatment of idiopathic faecal incontinence

Parameters which will identify patients who are likely to remain incontinent after abdominal rectopexy

K. Yoshioka and M.R.B. Keighley, *The General Hospital, Birmingham, UK*

We have studied 18 incontinent patients with a full-thickness rectal prolapse preoperatively, using anal manometry, saline infusion tests and videoproctography. Continence was restored in only 12 patients Persistent incontinence could not be identified by resting anal pressures (continent patients 57 cmH$_2$O (range 37–80), incontinent 46 cmH$_2$O (21–59)) or by maximum squeeze pressures (continent 84 cmH$_2$O (64–121); incontinent 73 cmH$_2$O (33–94)). The volume of the first leak during saline infusion was significantly lower in patients who remained incontinent (30 ml (10–40)) compared with those who became continent (80 ml (40–300); $P<0·025$) Median preoperative anorectal angles during maximum pelvic floor contraction were 106° (91–122) in patients whose continence was restored compared with 133° (131–152; $P<0·025$) in those who remained incontinent. Pelvic floor descent during straining was also significantly greater in patients who remained incontinent (4·8 cm (3·8–6·8)) compared with those who became continent (2·0 cm (0·9–4·3), $P<0·005$). The anal canal was shorter in the patients who remained incontinent (2·3 cm (1·2–3·1)) compared with the remainder (3·7 cm (3·6–6·2), $P<0·05$).

Using these criteria, it might be possible to select patients in whom postanal repair should be performed synchronously with abdominal rectopexy

The effect of photodynamic therapy on skeletal muscle and tumours using five different photosensitizers

E.B. Chevretton, M.C. Berenbaum*, R. Bonnett† and N.S Williams, *Department of ENT Surgery and the Surgical Unit, The London Hospital, *Department of Experimental Pathology, St Mary's Hospital Medical School, and †Department of Chemistry, Queen Mary College, London, UK*

Treatment of head and neck cancer poses special problems as the close proximity of structures in this region means that normal tissues may be damaged Exposure of photosensitized muscle to light causes rapid oedema and, if the damage is severe, necrosis Five photosensitizers, haematoporphyrin derivative (HpD), Photofrin II and the three isomers of the tetrahydroxyphenylporphyrins (*meta-*, *ortho-* and *para*-THPP), were compared for their ability to sensitize skeletal muscle and tumours BALB/c mice were given various doses of sensitizers Twenty-four hours later the posterior aspect of one lower leg was exposed to 10 J cm^{-2} of light of an appropriate wavelength from a copper vapour-pumped dye laser. Muscle damage was measured as percentage weight increase due to oedema at 4 h and percentage area necrosis at 48 h These results were compared with those obtained for depth of tumour necrosis in subcutaneous PC6 tumours in mice[1].

The THPPs were more potent than HpD and Photofrin II in causing both tumour necrosis and muscle damage. The table below is a cost–benefit analysis comparing the different photosensitizers in terms of muscle swelling and necrosis obtained for a given depth of tumour necrosis *m*-THPP produces significantly less muscle damage than HpD and Photofrin II for 3 and 4 mm of tumour necrosis and would be the sensitizer of choice in photodynamic therapy where muscle was liable to damage

	Percentage muscle swelling for 1–4 mm of tumour necrosis				Percentage muscle necrosis for 1–4 mm of tumour necrosis			
Sensitizer	1	2	3	4	1	2	3	4
m-THPP	6	7	9	10	18	22	30	48
o-THPP	6	12	18	26	nd	nd	nd	nd
p-THPP	7	9	20	26	12	40	77	91
HpD	18	35	46	46	33	55	>68	
'Photofrin II	10	44	>36		20	55	86	>86

1. Berenbaum MC, Akande SL, Bonnett R *et al.* *meso*-Tetra-(hydroxyphenyl)porphyrins, a new class of potent tumour photosensitisers with favourable selectivity. *Br J Cancer* 1986, **54**· 717–25

Inhibition of RT112 human transitional tumour xenografts by stearic and sterculic acids

B. Fermor, N.A. Habib, S.B. Kelly, C.B. Wood* and R.C.N. Williamson*, *Departments of Surgery, Bristol Royal Infirmary and *Royal Postgraduate Medical School, London, UK*

Oleic acid increases the growth of normal and malignant cells, stearic acid inhibits cell growth[1]. Saturated stearic acid is desaturated to mono-unsaturated oleic acid by the enzyme complex Δ^9-desaturase Sterculic acid, a cyclopropene fatty acid, inhibits the activity of this enzyme[2].

Male athymic MF1 nude mice received 5×10^6 RT112 tumour cells subcutaneously ($n=24$) and were randomly allocated to two equal groups Group I received 4 mg/ml stearic acid plus 2 mg/ml sterculic acid dissolved in 0·2 ml liquid paraffin subcutaneously twice weekly, group II (controls) received 0·4 ml liquid paraffin subcutaneously twice weekly

	Mean tumour volume (mm^3 ± s e m.)	
Day	Stearic + sterculic	Paraffin
13	10·2 ± 6·8	9·5 ± 4·2
22	48·7 ± 20·0	84·1 ± 19·6
34	147·0 ± 51·5	306·4 ± 100·1
42	164·2 ± 44·6*	495·9 ± 136·8

Significance *versus* controls $^*P=0·03$

Forty-two days after implantation of tumour cells, stearic and sterculic acids induced a significant reduction (66·9 per cent) in mean tumour volume compared with control animals ($P<0·05$) These data show the ability of stearic acid in combination with sterculic acid to significantly inhibit tumour growth *in vivo*.

Is the laser really necessary for successful photodynamic therapy?

M. Turkish, P. Durdey, M.F. Grahn, L. Ilincic, J.T. Allardice and N.S. Williams, *The Surgical Unit, The London Hospital, London, UK*

Photodynamic therapy is receiving increasing attention as a treatment for malignant disease However, the cost and maintenance of lasers is prohibitive and this may restrict its use in patients who are otherwise suitable.

We have therefore investigated alternative non-coherent light sources to determine whether a comparable cytotoxic effect can be achieved over similar time periods and irradiation doses. Red and green laser light were compared with theatre lights and daylight tungsten lamps. Multicellular tumour spheroids from the cell line HRT18 were pretreated with 10 μg/ml of haematoporphyrin derivative, and the cytotoxic effect of different light sources was measured using tritiated thymidine incorporation. Results are expressed as mean (±s e m) percentage inhibition.

Light source	Irradiance ($J\ cm^{-2}$)	Inhibition (%)
Red laser light	10 J/cm^2	54·7 (±6)*†
Green laser light	10	35·5 (±7)
Theatre lights	10	87·0 (±3·7)*
Tungsten daylight lamps	4·25	70·4 (±6·1)†

*,† $P<0·01$ by analysis of variance

For a given irradiance, growth inhibition of multicellular tumour spheroids was significantly greater with a polychromatic light source (theatre lights and tungsten daylight lamps) than laser light. Polychromatic light may not achieve as effective tissue penetration as does red light. However, for the ablation of superficial tumours and adjuvant treatment of the tumour bed peroperatively, the cheaper alternative of an adapted polychromatic light source (tungsten daylight lamps) may allow more widespread use in clinical practice.

Urokinase promotes the growth of a murine tumour in vivo

G.T. Layer and K.G Burnand, *Department of Surgery, St. Thomas' Hospital Medical School, London, UK*

Urokinase receptors are described on the plasma membrane of breast cancer[1] and murine melanoma cells[2] It is postulated that autocrine secretion of plasminogen-activating enzyme urokinase determines normal cellular growth and that malignant transformation is due to an excess of urokinase

The effects of intraperitoneal urokinase, intramuscular stanozolol (which affects tissue-type plasminogen activator levels) and oral aminocaproic acid (ε-ACA) on systemic and lung and kidney tissue fibrinolytic activity in groups of ten C57Black mice were investigated These drugs were also administered to mice inoculated subcutaneously with Lewis lung carcinoma to determine whether exogenous urokinase or drugs altering fibrinolysis affect tumour growth

Significant differences in systemic activity measured by euglobulin clot lysis (ECLT) were detected between all groups No differences in tissue activity were found

Table 1

		Urokinase	Stanozolol	ε-ACA	Controls
ECLT (min)	median	70	215	15·5	28
	range	35–120	120–280	11–35	16–50
$\frac{10^6}{(ECLT)^2}$	mean	270	37	4934	1589

One way analysis of variance $F=16·1$, $P<0·01$

There was a significant increase in the primary tumour weights arising for urokinase and stanozolol treated groups compared with controls. Pulmonary metastases were also increased by urokinase

Table 2

Weight (g)	Urokinase	Stanozolol	ε-ACA	Controls
Primary tumour	2·53±0·33*	2·57±0·33*	1·18±0·21	1·15±0·14
Metastases	27·9±6·3†	27·0±9·1	20·3±4·0	14·5±3·7

Data are means±s.e m., * $P<0·004$, † $P<0·043$, *versus* controls (Mann–Whitney U tests)

It is concluded that urokinase-type plasminogen activator promotes growth of Lewis lung carcinoma *in vivo* Its effect is similar to stanozolol and may be mediated by urokinase receptors, causing direct cellular changes or an effect on tumour-associated fibrin This provides further support for a role for plasminogen activators and fibrinolysis in malignancy

Tumour-cell DNA content in squamous carcinoma of the head and neck: prediction of response to chemotherapy

L.D. Cooke, T G. Cooke, G. Forster, T.R. Helliwell, D. Spiller and P.M. Stell, *Departments of Otorhinolaryngology, Surgery, Pathology and Radiation Biology, University of Liverpool, UK*

In two phase III trials we have shown that cisplatinum significantly prolongs survival in patients with end-stage squamous carcinomas of the head and neck region[1]. Factors such as performance status, age, site, nodal status, and serum albumin are prognostic factors but are not significantly clear-cut to define which patient should be treated In an attempt to improve on this we have measured tumour cellular DNA in this sample group

We studied tumours from 41 untreated patients and 52 patients receiving cisplatinum as part of a prospectively randomized trial Sections of tumour of 50 μm thickness were enzymatically disaggregated, treated with RNAase, and the DNA stained with propidium iodide Following analysis by flow cytometry they were classified as diploid or aneuploid

Fifty-four per cent of all tumours were aneuploid and 46 per cent diploid, with similar proportions in both treated (57.43 per cent) and untreated patients (51·49 per cent) Survival time with diploid tumours increased from 68 days for untreated patients to 128 days after chemotherapy, but this difference was not significant ($\chi^2=1·91$) However, the survival of patients with aneuploid tumours increased fourfold from 55 to 224 days ($\chi^2=10·29$, $P<0·001$)

This study suggests that cisplatinum chemotherapy in end-stage head and neck cancer should be restricted to patients with aneuploid tumours

Are there oestrogen receptors in pancreatic carcinoma?

O.M. Taylor , J Harrison†, P.N. Cowen*, M.J. McMahon and E.A. Benson; *Departments of Surgery and *Histopathology, General Infirmary, Leeds, and †Queens Medical Centre, Nottingham, UK*

Recent reports have suggested the presence of oestrogen receptors in pancreatic carcinomas If true, there is the potential for treatment by hormone-manipulation techniques, there have been suggestions of benefit in patients treated with tamoxifen[1].

Biopsies of human pancreatic adenocarcinoma were examined for the presence of receptors to oestradiol, using three techniques. (1) iso-electric focusing (IEF); (2) ERICA, using a monoclonal antibody to oestrophilin (the oestrogen receptor protein), and (3) ERD-5, using a monoclonal antibody to a cytoplasmic oestrogen receptor-associated protein A slice of tissue demonstrated histologically to contain tumour was tested in each case

Twenty-five biopsies were assayed with ERICA, 13 with ERD-5, and nine by IEF Using ERICA and IEF all were negative for oestrogen receptors Using the ERD-5 all were positive, as well as two biopsies containing normal pancreas

Pancreatic carcinoma tissue has been reported to contain oestrogen receptors, detected using biochemical assays[2] We were unable to demonstrate receptors with IEF, or with the more sensitive ERICA ERD-5 has been reported to correlate poorly with other assays of oestrogen receptors in breast tissue

These results suggest that oestrogen receptors are not present in pancreatic carcinoma, or that the receptor present is of a different type to that found in breast and uterine tissue. Failure to demonstrate a specific oestradiol receptor suggests that a clinical response to tamoxifen is unlikely

Metastatic tumour growth in the regenerating liver

M. Loizidou, A. Cooper, R. Lawrence, P. Alexander and I. Taylor, *University Surgical Unit, Southampton, UK*

Metastatic growth occurs preferentially at sites of trauma , e.g healing wounds, anastomoses[1] and damaged liver[2]. We have studied the role of parenchymal liver regeneration on the growth of tumour cells delivered intraportally

In control rats, 2×10^5 intraportally injected syngeneic MC28 sarcoma cells gave rise to minimal tumour in the liver (<2 superficial foci in 10/25 rats). If these cells were injected from 15 min to 2 days after partial (two thirds) hepatectomy, tumour grew in all cases (n=40), almost invariably at the resection site Stimulation of DNA synthesis, as measured by uptake of [^{3}H]thymidine, was effectively complete by 4 days When MC28 cells were injected 5–7 days after hepatectomy, tumour did not grow at the resection site, many foci appeared not only superficially but also predominantly within the regenerated lobe (>20 foci in 30/30 rats) Cells injected 10 days after hepatectomy yielded levels of tumour foci similar to the control.

We conclude that promotion of tumour growth in partially hepatectomized rat livers is caused by at least two mechanisms, one related to trauma and the other to a delayed effect of regeneration

The effect of a gastrin receptor antagonist on the growth of gastrin-responsive primary human colorectal tumours

S.A. Watson, L.G. Durrant, R. Chadderton* and D L. Morris*, *Department of Cancer Research, Nottingham University, and *Department of Surgery, University Hospital, Nottingham, UK*

A series of 40 colorectal human tumours was screened for their growth response to gastrin (assessed by ^{75}[Se]selenomethionine incorporation) Of the colorectal tumours 57·5 per cent responded trophically to the hormone Low numbers of gastrin-binding sites (from 1×10^2 to 1×10^3/cell) could be detected in 50 per cent of all tumours using ^{125}I-labelled gastrin in a radioimmunoassay.

If the growth of human colorectal tumours is gastrin-dependent (possibly autocrine/paracrine) then gastrin receptor antagonists should reduce the growth of such tumours. A potent gastrin receptor antagonist (with the same affinity for the receptor as gastrin) significantly reduced the *in vitro* growth in four of six colorectal tumours (as measured by label incorporation), and reduced the *in vitro* response to gastrin in three of six colorectal tumours Gastrin receptor antagonists may be potential therapeutic agents for treatment of such tumours

Prospective study of 'risk' of gastric cancer in new onset dyspeptic patients, comparing a simple scoring index with a clinician's assessment

E.M. Chisholm, B.J. Unwin, A.G. Morgan and G.R. Giles, *Department of Surgery, St. James's Hospital, Leeds, and Airedale Hospital, Keighley, UK*

To decrease the mortality rate for gastric cancer patients, more cases of potentially curable cancer must be found. A simple scoring index to indicate 'risk' of gastric cancer in a dyspeptic population and therefore to determine priority for endoscopy has been evaluated in a prospective study of 300 consecutive referrals to a dyspepsia clinic over a 2-year period

Each patient answered eight critical gastrointestinal questions, using a previously validated scoring index, the risk of cancer was ascribed as high (probability P>0·05), intermediate, or low (P<0·0018) Unaware of this risk assignment, the clinicians recorded their assessment. All patients underwent gastroscopy and ultrasound examination Mean follow-up was 32 months (range 18–42).

Sixteen patients presented with gastric cancers Fifteen cancers (eight curable) were identified as high risk by the scoring index compared with nine (five curable) cancers defined by the clinician The specificity and positive and negative predictive yields were very similar for both the scoring index and the clinician· 28 per cent of patients were identified as low risk by both assessors and confirmed upon investigation To date no further cancer has arisen in the remaining patients.

A simple risk index for gastric cancer using symptom analysis can predict cancer risk as accurately as a clinician, with a high yield per endoscopy, and may therefore be useful in determining priority for endoscopy to detect potentially curable gastric cancer.

Why is anti-reflux surgery superior to medical treatment for refractory gastro-oesphageal reflux?

S.J Walker, S. Holt, C J. Sanderson and C J. Stoddard, *University Department of Surgery, Royal Liverpool Hospital, Liverpool, UK*

It is unknown why a minority of patients with gastro-oesophageal reflux fail on medical treatment yet have a successful outcome after anti-reflux surgery. In order to investigate this we prospectively studied 16 patients (14 men) mean age 50 years (range 36–73) with prolonged, refractory reflux whilst on medical treatment and continued to study them after anti-reflux surgery. Patients were assessed before treatment by symptom scoring, endoscopy, manometry and ambulatory oesophageal pH monitoring. Symptoms and pH were assessed on treatment with ranitidine 150 mg b.d. alone for 1 week, and again with ranitidine plus metoclopramide 10 mg t.d s. for a further week Reassessment was performed 3 months after transabdominal surgery (Nissen, 9, Lind, 7) Six parameters of reflux were examined at 5 pH levels by 22-h pH monitoring (Ormed) Surgery significantly improved the median results at all pH levels compared with no treatment whilst medical management only improved results at some levels.

Treatment	Upright (%)†	Supine (%)†	Reflux	Reflux 5 min
No treatment	17·1 (8·5, 23·4)	17·4 (8·0, 44·0)	34 (21, 52)	12 (5, 18)
Ranitidine	13·0 (6·5, 20·0)	8·4 (0·1, 18·6)*	34 (21, 42)	19 (1, 12)*
Ranitidine + metoclopramide	8·9 (4·7, 15·2)*	4·9 (1·2, 14·5)*	24 (16, 39)	6 (3, 10)**
3 months after surgery	3·6 (1·2, 9·9)**	1·4 (0·0, 9·0)*	10 (2, 19)**	4 (1, 6)**

*P<0·05, **P<0·01, Wilcoxon signed-rank test at pH 4 †Results are the percentage of time at pH <4; values in parentheses are ranges

There was no significant difference between ranitidine alone or in combination with metoclopramide Surgery was superior to medical treatment (P<0·05) for the control of upright reflux and for all reflux episodes, and more frequently produced pH results in the normal range. Significant improvements in symptoms occurred after surgery (P<0·05, χ^2), giving more complete control of acid reflux than did medical treatment in refractory gastro-oesophageal reflux.

The effect of introducing endoscopic therapy on surgery and mortality rates for peptic ulcer haemorrhage: a single centre experience of 1102 cases

G.M. Fullarton, G.G. Birnie and W R. Murray, *University Department of Surgery, Western Infirmary, and Department of Medicine, Gartnavel General Hospital, Glasgow, UK*

The introduction of early endoscopic diagnosis has not been associated with a reduction in either surgical intervention or overall mortality for peptic ulcer haemorrhage. Recent studies have suggested that endoscopic therapy (endostasis) can reduce rebleeding rates from peptic ulceration. We report a 2-year experience of the influence of endoscopic heater probe (Olympus CD 10Z) therapy on the outcome of patients admitted with peptic ulcer haemorrhage Eight hundred and sixty-two patients admitted with peptic ulcer haemorrhage over a 5-year period (1978/9–1983/5) before endoscopic therapy and 240 patients admitted with peptic ulcer haemorrhage after the introduction of endoscopic therapy (1986–8) were assessed. All the 1102 patients were managed by a joint physician/surgeon team Results for patients with duodenal ulceration and gastric ulceration are shown in the table

	Duodenal ulcers		Gastric ulcers	
	Surgery	Mortality	Surgery	Mortality
Before endostasis (n=862)	55/614 (9%)	18/614 (2·9%)	40/248 (16%)	22/248 (8·9%)
After endostasis (n=240)	9/132 (6·8%)	1/132 (0·8%)	8/108* (7·4%)	3/108* (2·8%)

* P<0·05

The introduction of an endostasis technique to the management of patients with peptic ulcer haemorrhage has been associated with a significant reduction in the surgical intervention rate and overall mortality for gastric ulceration. A similar but non-significant trend has been observed for duodenal ulcer haemorrhage.

Acid, motility and ulcers: a nature study

D.D. Kerrigan, L.A. Houghton, N.W. Read and A.G. Johnson, *University Department of Surgery, Royal Hallamshire Hospital, Sheffield, UK*

Disordered gastroduodenal motility may be implicated in the pathogenesis of duodenal ulceration by promoting prolonged acid contact with the duodenum. Using a multilumen perfused catheter, we recorded pressure activity in the antrum (two sites), pylorus (Dent sleeve) and duodenum (five sites) in 31 subjects: ten with active ulceration, eight healed and 13 healthy volunteers. Intraluminal pH was measured simultaneously in the antrum and duodenum (two sites), correct pH probe/catheter position was continuously verified by measuring transmucosal potential difference at either end of the Dent sleeve. Fasting pH and motor activity recordings for a mean of 75 min (standard error ±3 min), were continued for 224 ± 18 min after ingestion of a 128 g radiolabelled beefburger.

During fasting, the percentage of time that pH fell to <4 in the duodenal bulb was greater in healed than in active ulcers (12·6 per cent (0–46 per cent) *versus* 0·7 per cent (0–22 per cent), median (range), $P = 0·03$). Bulb pH was <4 for 16 per cent (1–54 per cent) of the postprandial period in healed ulcers, compared with 3 per cent (0–20 per cent) in controls and 1·7 per cent (0–8 per cent) in active ulcers (healed *versus* active $P = 0·04$). Emptying of the antrum after ingestion of the beefburger was significantly delayed in healed duodenal ulcer subjects (healed $T_{50} = 197$ min, control $T_{50} = 137$ min, $P = 0·02$) and associated with a trend to antral hypomotility. Active ulcer subjects and controls emptied at similar rates, indicating that impaired gastric motility in healed duodenal ulceration is secondary to increased duodenal acidification. Differences in bulb pH in active and healed ulcers may also explain the typical cycle of spontaneous healing, yet frequent relapse.

Ischaemic injury and acid back-diffusion may be synergic in acute gastric stress ulceration

R. Stuart, T.F. Gorey, E. Kay, P.J. Byrne and T.P.J. Hennessy, *Trinity College Dublin Department of Surgery, St James's Hospital, Dublin, Ireland*

Mucosal ischaemia with accumulation of oxygen free radicals may be a cause of stress ulceration. We have investigated the efficacy of allopurinol (xanthine oxidase inhibitor) and cimetidine in the prophylaxis of stress ulceration. Pylorus-ligation and gastric-fistula models used previously for acid secretion studies are unphysiological.

Wistar rats of mean weight $193 \pm 4·2$ g were stressed by restraint at 4°C for 2 h and gastric pH was monitored continuously with a modified antimony pH probe and corroborated by serial serum gastrin levels. Rats were divided into four groups of 12, which were given: (a) 1 ml normal saline per os (controls), (b) cimetidine 50 mg/kg intramuscularly, (c) allopurinol 15 mg/kg per os, and (d) allopurinol 5 mg/kg intravenously. After killing, gastric lesions were assessed histologically, measured with a microscope eyepiece graticule, and an ulcer index calculated from the product of ulcer numbers and grade.

			Allopurinol	
	Control	Cimetidine	Oral	Intra-venous
Ulcer index	$59·4 \pm 7·7$*	$10·1 \pm 2·01$	$13·5 \pm 2·48$	$5·8 \pm 1·8$
Gastric pH				
Before drug		$2·4 \pm 0·4$	$2·48 \pm 0·27$	$2·86 \pm 0·26$
Before stress	$2·95 \pm 0·26$	$5·6 \pm 0·48$*	$3·03 \pm 0·31$	$3·08 \pm 0·21$
After stress	$2·6 \pm 0·43$	$5·33 \pm 0·5$*	$1·8 \pm 0·22$	$2·67 \pm 0·48$

All values are means ± s.e.m., * $P < 0·01$, Student's *t* test

Serum gastrin (pmol/l) remained unaltered by stress in the control (before $35·6 \pm 3·54$, after $46·3 \pm 7·42$) and allopurinol (before $33·5 \pm 3·68$; after $44·3 \pm 7·28$) groups, but was significantly elevated in cimetidine-treated rats (before $26·67 \pm 2·13$, after $88·1 \pm 12·85$, $P < 0·01$).

Allopurinol prevents stress ulceration without manipulation of gastric pH. It is suggested that this may be achieved by inhibition of xanthine oxidase-dependent free radical production during mucosal ischaemia which, after the compromise of barrier integrity, may allow acid back-diffusion.

An evaluation of modified sham feeding as a test for completeness of vagotomy

I.G. Martin, M.J. Rogers and D. Johnston, *University Department of Surgery, The General Infirmary, Leeds, UK*

The insulin test has been well documented as a test for completeness of vagotomy. However, the stimulus to acid secretion produced by insulin is not purely vagal in nature and insulin hypoglycaemia is not without hazard. The use of a modified sham feed chew and spit technique has been evaluated in 37 patients undergoing highly selective vagotomy for duodenal ulcer.

Before operation, all 37 patients had BAO, PAO^{Pg}, and PAO^{SF} measured. From 7 to 9 days after operation BAO, and PAO^{SF} and, on another day, BAO and PAO^{I} were measured. Before operation (vagi intact), a median increase in hydrogen ion concentration of 29 mmol/l (upper quartile (UQ) 35 mmol/l, lower quartile (LQ) 20 mmol/l) occurred within 45 min of starting sham feeding. Median PAO^{SF} was 18 mmol/h (UQ 27, LQ 12). After vagotomy, PAO^{I} correlated well with PAO^{SF} (Rank Spearman = 0·53, $P < 0·001$). Using Hollander's criteria, eight insulin tests were positive (1 early, 7 late). Using a rise of 15 mmol/l to indicate incomplete vagotomy, 10 of the sham feeding results were positive (6 positive, 4 negative insulin tests). The median acid response to sham feeding (minus BAO) after vagotomy was 0 mmol/h (UQ 0·16, LQ 0), nine patients had an increase of >0·5 mmol/h and five an increase of >1 mmol/h, all nine were also positive on the concentration response to sham feeding. Two patients have developed recurrent ulcer: both were insulin positive and both on sham feeding had an increase in acid concentration of >15 mmol/l and both had an acid response of >0·5 mmol/h.

In conclusion, sham feeding correlates with the insulin test and incomplete vagotomy is indicated by a rise in concentration >15 mmol/l or an increase in acid output of greater than 0·5 mmol/h, providing a safe and well tolerated alternative to the insulin test.

Oesophageal dysmotility in symptomatic reflux patients with normal endoscopy and pH profile

C.A. Eriksen, P.T. Cullen, D. Sutton, N. Kennedy and A. Cuschieri, *Departments of Surgery and Nuclear Medicine, Ninewells Hospital and Medical School, Dundee, UK*

There is a well known cohort of patients who, despite classical reflux symptoms, have a normal oesophageal pH profile and endoscopy. The management of these patients has proved problematic. In an attempt at determining the pathophysiology of this subgroup, we investigated the oesophageal transit, using a radiolabelled solid egg bolus technique[1] in 58 such patients: 25 men, 33 women, mean age 39·5 years (range 13–65).

The egg transit was normal in 30 patients (52 per cent). In the remaining 28 patients (48 per cent), the condensed image analysis showed the following specific abnormal transit patterns[2]: 'step' delay pattern, demonstrating segmental hold-up in mid- or distal oesophagus in 16 (57 per cent), non-specific delay in six (21 per cent), oscillatory pattern in three (11 per cent), and total non-clearance during the study period (4 min) in three (11 per cent). No significant correlation was found between transit pattern and symptom score (heartburn, Tau −0·115; regurgitation, Tau −0·013, dysphagia, Tau 0·097, Kendall correlation coefficient).

This study shows that almost 50 per cent of patients with reflux symptoms and negative pH and endoscopy have abnormal oesophageal transit, and almost two-thirds of these abnormal patients display segmental transit delay in the lower half of the oesophagus. The effect on symptomatology by prokinetic agents in this patient sub-group needs evaluation.

Is the oesophageal body more important than the lower oesophageal sphincter in the pathogenesis of reflux oesophagitis?

L.R. Jenkinson, T.L. Norris and A. Watson, *Department of Surgery, Royal Lancaster Infirmary, Lancaster, UK*

DeMeester[1] has shown that manometric techniques can be used to detect an incompetent lower oesophageal sphincter (pressure ≤6 mmHg, intra-abdominal length <1 cm or sphincter length <2 cm). Similarly, recent combined fluoroscopic and manometric studies have shown that oesophageal clearance is prolonged when peristaltic amplitude is <30 mmHg in the distal oesophagus[2] We have investigated the manometric function of the lower oesophageal sphincter and distal oesophagus using these definitions of incompetence to assess the role of each in the pathogenesis of gastro-oesophageal reflux and their relationship to a hiatus hernia.

A consecutive series of 64 patients with gastro-oesophageal reflux or its complications were evaluated using perfusion manometry. Thirty-seven patients (58 per cent) had peristaltic failure, 29 (45 per cent) had an incompetent cardia and 47 (73 per cent) had a hiatus hernia; 38 (59 per cent) had a combined oesophageal abnormality and a hernia, all three being present in 18 (28 per cent). Isolated incompetence of the cardia in two patients (3 per cent) or peristaltic failure in six (9 per cent) were uncommon. A hernia was the only abnormalty in nine patients (14 per cent) Overall 56 patients (88 per cent) had a manometric defect or a hernia.

This study has shown that peristaltic failure is the most common oesophageal abnormality in patients with gastro-oesophageal reflux. This suggests, contrary to current belief, that the distal oesophagus may be the main protective mechanism and not the lower oesophageal sphincter

Monoclonal antibody staining of benign breast tissue components acts as a marker for breast carcinoma

S.P. Courtney, S. Williams and R.E. Mansel, *Departments of Surgery and Pathology, University of Wales College of Medicine, Cardiff, UK*

Monoclonal antibodies 323A3 and Ca1 have been suggested as markers of cancer risk in benign breast disease. The staining characteristics of these antibodies have been studied in ducto-lobular and apocrine tissue in 79 patients with breast carcinoma and in 77 patients with benign breast biopsies.

All the sections studied contained ducto-lobular tissue. Apocrine metaplasia was located in 35 of the malignant biopsies and 42 of the benign biopsies

323A3 antibodies stained strongly the cytoplasm of apocrine metaplasia associated with breast cancer biopsies in 18 of 35 cases, whereas in the benign biopsies only 2 of 42 stained strongly. This difference was statistically significant ($P<0{\cdot}001$, χ^2). By contrast, apical membrane-staining of apocrine tissue by Ca1 antibodies was strong in all 42 benign biopsies, but only 23 of 35 stained strongly in the malignant group ($P<0{\cdot}001$, χ^2).

Malignant breast disease is associated with enhanced expression of the 323A3 antibodies but inhibits expression of Ca1 antigen in apocrine metaplasia. If these changes pre-date the development of overt malignancy they may be useful as markers of breast cancer risk.

Does choice of treatment affect psychological morbidity in early breast cancer? A three-year prospective study

L.J. Fallowfield, A Hall, M. Baum and P.G. Maguire, *CRC Clinical Trials Centre, King's College Hospital, London, UK*

Psychiatric morbidity following mastectomy has been well documented Assumptions that the primary cause is breast loss have not been supported by psychological studies comparing mastectomy with breast-conserving procedures[1] Women who have lumpectomy followed by radiotherapy also experience affective disorders due to fear of cancer and possible recurrence There is evidence that giving women choice concerning treatment options reduces psychiatric morbidity[2,3], although studies to date are small, with short-term follow-up We report preliminary data from a prospective study of 268 women with early breast cancer treated at 10 centres The participating surgeons are grouped according to whether they offer as primary therapy mastectomy, lumpectomy, or a choice of treatment wherever possible

Rates of anxiety and depression were high postoperatively and 3 months later amongst patients of surgeons preferring mastectomy and lumpectomy, irrespective of the actual treatment performed. These rates were considerably lower amongst the patients of 'choice' surgeons where morbidity was largely attributable to those patients unable to exercise choice for 'technical' reasons

These results must be viewed cautiously. giving patients more responsibility for treatment decisions means that they may also feel responsible for outcome, especially if disease progresses. The effect that choice of treatment has on psychological morbidity can only be assessed with long-term follow-up

A randomized controlled trial of medroxyprogesterone acetate in mastalgia

P.R. Maddox, B.J. Harrison, R.E. Mansel, J.M. Horrobin* and P.E. Preece*, *University Departments of Surgery, Cardiff and *Dundee, UK*

There is currently much controversy on the role of luteal deficiency and progesterone replacement in the treatment of mastalgia[1], but no controlled trial has been reported We have carried out a double-blind controlled cross-over study giving 20 mg of medroxyprogesterone acetate (MPA) daily to 26 patients over a period of 6 months. Symptomatic response was assessed objectively by clinical examination and subjectively by a linear analogue scale

Eight patients withdrew from the study during the 6 months of treatment. four were on placebo, one had intolerable side-effects, one became pregnant, and two were non-compliant. The remaining 18 patients showed no significant relief of pain or tenderness on placebo or active treatment, irrespective of the order of treatment

	Clinical score	Linear analogue scale	
	Tenderness mean ± s.d.	Tenderness mean ± s d. (mm)	Pain mean ± s d (mm)
MPA-first group (*n* = 9)			
Pre-trial	2·0 ± 0·5	79·7 ± 26·4	74·7 ± 28·2
End of MPA period	1·7 ± 0·7	61·9 ± 33·6	58·1 ± 34·7
End of placebo period	1·9 ± 0·8	56·9 ± 38·8	43·3 ± 33·2
Placebo-first group (*n* = 9)			
Pre-trial	2·0 ± 0·7	88·3 ± 8·3	78·4 ± 13·6
End of placebo period	1·9 ± 0·8	71·4 ± 28·2	55·9 ± 30·9
End of MPA period	2·1 ± 0·9	63·0 ± 35·4	56·4 ± 37·9

There was no significant difference in MPA scores when compared with pre-trial or after placebo. Also no evidence of progesterone deficiency or prolactin abnormality was found on evaluation of serum taken before and both on and off therapy. Side-effects occurred in 11 patients (five on placebo, five on active treatment and one whilst on both) and were mostly vague premenstrual symptoms

We conclude that the therapeutic response of MPA in cyclical mastalgia is no better than placebo, and that progestogen supplementation can no longer be recommended for routine use in the management of breast pain

1. Sitruk-Ware R, Sterkers N, Mowszowicz I *et al.* Inadequate corpus luteum function in women with benign breast disease *J Clin Endocrinol Metab* 1977; **44** 771–4

The pro-enzyme form of urokinase: an important factor in human malignant breast disease?

D.A.P. Cooke, M. Mahmoud-Alexandroni*, P.J. Gaffney* and K.G. Burnand, *Department of Surgery, United Medical and Dental Schools, St Thomas' Hospital, London and *National Institute of Biological Standards and Control, Potters Bar, Hertfordshire, UK*

Tissue urokinase (uPA) activity is linked with malignancy. Cells produce uPA as a single-chain pro-enzyme (sc-uPA) which does not bind with plasminogen activator inhibitor (PAI) A high-affinity cell-surface receptor has been identified which binds sc-uPA It has been suggested that bound sc-uPA is converted to two-chain urokinase (tc-uPA) which is protected from PAI, unlike the rapidly inactivated free tc-uPA, and that on the cell surface the tc-uPA can modulate cellular processes or produce fibrinolysis in the micro-environment.

We examined sc-uPA activity in 45 breast biopsies (23 malignant, 22 benign). Cryofragmented samples were extracted into buffered saline and the plasminogen activators were estimated by bioimmunoassay. The sc-uPA was captured by a highly specific monoclonal antibody and detected by a chromogenic substrate solution. A similar system was used to measure tc-uPA activity.

Results shown in the table are in units/mg protein. There was a highly significant difference between the benign and the malignant biopsies in tc-uPA ($t=3{\cdot}582$, d.f. $=43$, $P<0{\cdot}01$) but it was even greater for sc-uPA ($t=5{\cdot}940$, *d.f.* $=43$, $P<0{\cdot}0001$).

	Benign	Malignant
sc-uPA		
Mean	0·155	0·766
Median; range	0·100, <0·1–1·301	0·659, <0·1–2·597
tc-uPA		
Mean	0·398	1·709
Median; range	0·139; <0·015–1·559	1·501, 0·023–6·630

These data support the hypothesis that sc-uPA may be more relevant in malignant breast disease than tc-uPA. Further studies on sc-uPA and its receptors are necessary to show whether the pro-enzyme is a prognostic determinant.

Humorally mediated bone resorption in breast cancer

M.R. Zeiderman, K. Rogers, M. Beneton and J.A. Kanis, *University Departments of Surgery and Human Metabolism, Northern General Hospital and Royal Hallamshire Hospital, Sheffield, UK*

There is a poor correlation between the extent of metastatic disease and the occurrence and severity of hypercalcaemia of malignancy. Recent reports of increased renal tubular reabsorption of calcium[1] and the identification of a PTH-like peptide from patients with non-metastatic cancer[2] suggest that hypercalcaemia and bone disease may be partly humoral in origin. For this reason we have looked for histological evidence of PTH-like activity in the bone of women with non-metastatic breast cancer at the time of their first presentation.

Eight women (mean age 45 years) were studied. None had clinical, radiological or scintigraphic evidence of skeletal metastases. Transiliac bone biopsies were obtained by trephine at the time of definitive breast surgery. Quantitative bone histology[1] was compared with measurements from eight women without breast disease who had recently been admitted for cholecystectomy.

Resorption surfaces of bone were significantly greater in the patients with breast cancer than in controls (rough crenated surface $17{\cdot}0\pm1{\cdot}9$ *versus* $9{\cdot}5\pm0{\cdot}9$ mm per cent total trabecular surface (TTS), $P<0{\cdot}003$ Mann–Whitney U, reversal surface $14{\cdot}6\pm1{\cdot}7$ *versus* $8{\cdot}1\pm0{\cdot}7$ mm per cent TTS, $P<0{\cdot}003$). In addition, the rate of bone formation, as judged by *in vivo* tetracycline labelling, was lower in breast cancer patients ($0{\cdot}028\pm0{\cdot}002$ *versus* $0{\cdot}038\pm0{\cdot}007$ per cent TTS).

These data provide further evidence for the existence of humoral factors in breast cancer capable of influencing bone metabolism even at an early stage of disease.

The role of tamoxifen in the primary management of elderly women with breast cancer

T. Bates, D.L. Riley, J. Houghton and M. Baum (on behalf of the Elderly Breast Cancer Working Party), *CRC Clinical Trials Centre, King's College School of Medicine and Dentistry, London, UK*

Patients over the age of 70 have been randomly selected for treatment by either tamoxifen alone (40 mg daily, $n=170$) or 'optimal' surgery plus tamoxifen ($n=163$), with a median follow-up of 34 months.

As progression in the conservatively treated group cannot be compared with local recurrence in the surgical group, 'changes of management' (COM) have been recorded. Forty-four (26 per cent) COM have been observed in the group receiving tamoxifen alone, 36 being due to local or regional progression, 27 (61·4 per cent) underwent subsequent surgery. In the surgical group 29 patients (18 per cent) had COM, 17 being due to local or regional recurrence, 19 (66 per cent) underwent further surgery.

Of the conservatively treated group, 126 are assessable for measurement of tumour response, 19 of these (15 per cent) obtained a complete remission by 6 months, and in 28 (22 per cent) 'best ever response' was observed. The latter was recorded for 16 patients who gained a partial remission (13 per cent), 68 (54 per cent) with static disease and 14 (11 per cent) with progression (tumour >25 per cent initial size). Almost 90 per cent of the conservatively treated group have been maintained for at least 6 months by tamoxifen therapy alone, although more have subsequently undergone a change of management. There is no difference in survival.

In contrast to the two contradictory reports on the primary management of breast cancer in the elderly already published[1,2], we feel it is premature to make firm therapeutic recommendations.

An evaluation of triple-node biopsy in staging breast cancer

R.S. du Toit, A.P. Locker, C.W. Elston, I.O. Ellis and R.W. Blamey, *Nottingham City Hospital, Nottingham, UK*

Six hundred and ninety-three patients with early breast cancer treated by primary surgery and a triple-node biopsy technique of the draining lymph nodes have been reviewed to determine the prognostic value of adding the apical and/or internal mammary node to sampling of the lower axillary nodes. One node each was sampled from the lower axilla, the apex of the axilla and the second intercostal space.

Results showed that the positive node rate of each node location increased with an increase in tumour size. Lateral tumours (70 per cent) gave significantly more positive lower axillary and apical nodes than medial tumours. Medial tumours (15 per cent) gave significantly more positive internal mammary nodes than lateral tumours. No differences in node positive rates between apical and internal mammary nodes could be found for centrally located tumours.

Cases with a positive apical node had been shown previously to have a poor prognosis. Involvement of the internal mammary node alone was associated with the same prognostic value as involvement of the lower axillary node alone. When both of these two nodes were positive the prognosis deteriorated to that of a positive apical node.

Additional prognostic information was gained in 12·8 per cent of cases with laterally located tumours if the apical node was sampled in addition to that of the lower axilla; and in 17·6 per cent of cases with medially located tumours if the internal mammary node was sampled in addition to the lower axillary node.

The prognostic information gained justifies the policy of triple-node biopsy.

Relationship of in vitro response to gastrin, gastrin receptor status and ability to secrete gastrin in gastrointestinal cancer cells

S.A. Watson, L.G. Durrant and D.L. Morris*, *Department of Cancer Research, Nottingham University, and *Department of Surgery, University Hospital, Nottingham, UK*

A series of gastrointestinal tumour cell lines were screened for their *in vitro* growth response to human gastrin (G–17) by ^{75}[Se]selenomethionine incorporation.

In vitro growth response was shown in a rat pancreatic (AR42J) and a human gastric (MKN45) cell line which responded to G–17 by enhanced label incorporation (195 and 145 per cent of control). Of three human colorectal cell lines examined, HT29 responded moderately (123 per cent) whereas C280 and C146 did not respond to the hormone.

Gastrin receptors were measured in the above cell lines using ^{125}[I]G–17. AR42J had $1{\cdot}5\times10^5$ specific gastrin-binding sites per cell, MKN45 had 3×10^3, and the colorectal lines had no measurable sites.

Gastrin production by the cell lines during *in vitro* growth was analysed by a radioimmunoassay using an antigastrin antiserum. An inverse relationship between gastrin response and gastrin production *in* *vitro* was observed. No gastrin was detected in the cell culture medium after growth of AR42J (the most gastrin-responsive cell line) whereas 44 to 37 ng litre^{-1} cells^{-5} per day of gastrin was measured in the medium after growth of C146 and C280 (non-gastrin responsive cell lines). MKN45 responded to and produced modest levels of gastrin (11·5 ng litre^{-1} cells^{-5} day^{-1}). Gastrin receptor status appears to be correlated with the ability of cancer cells to respond to gastrin but perhaps inversely to their ability to secrete gastrin.

Glucocorticoids mediate the catabolic effects of tumour necrosis factor during critical illness

K. Mealy, J.J.B. Van Lanschot and D.W. Wilmore (introduced by T.P.J. Hennessey), *Department of Surgery, Brigham, and Women's Hospital and Harvard University, Boston, USA*

Cytokines and hormonal mediators contribute to the metabolic response of critical illness. To investigate the interaction between these agents, we administered tumour necrosis factor (TNF: 0, 2 and 4×10^5 units kg^{-1} 24 h^{-1}) to 40 male Wistar rats to determine the adrenal response. Adrenal weight increased with dose of TNF ($P<0·001$). We then administered TNF (2×10^5 units kg^{-1} 24 h^{-1} intravenously) or corticosterone (CC, 75 mg pellets subcutaneously) to rats maintained on a constant intravenous diet over 7 days. Daily nitrogen balance was determined and organ and carcass composition measured at the time of killing. A portion of the data is shown (mean ± s.e.m.)

	Control ($n=9$)	CC ($n=7$)	TNF ($n=11$)
Carcass nitrogen (g)	2·58 ± 0·09	2·06 ± 0·18	2·19 ± 0·10*
Liver nitrogen (mg)	268·4 ± 19·0	283·0 ± 7·9	440·0 ± 30·0*†
Ureagenesis (mg 6 days^{-1})	1428 ± 92	2280 ± 209*	2182 ± 115*
Nitrogen balance (mg 6 days^{-1})	987 ± 91	125 ± 209*	224 ± 123*
Jejunal mucosal DNA (µg cm^{-1})	141·2 ± 11·8	124·4 ± 11·7	87·3 ± 7·0*†
Jejunal mucosal protein (mg/cm)	1·86 ± 0·17	1·80 ± 0·19	1·3 ± 13*†

* $P<0·01$ *versus* control († $P<0·01$ *versus* CC) by ANOVA (Dunnett *t* test).

Plasma corticosterone in CC and TNF groups were similar when the rats were killed (24·8 ± 2·7 *versus* 16·1 ± 2·2 µg dl^{-1}). Both CC and TNF increased peripheral proteolysis as determined by decreased carcass nitrogen content and diminished nitrogen balance. TNF alone increased liver mass and caused substantial destruction of the intestinal tract. TNF mediates many of the major metabolic sequelae of critical illness. However, its effects on skeletal muscle can be explained by activation of the hypothalamic/adrenal stress response.

Taurolidine improves survival in rats with established peritonitis

P.D. Carey, T.M. Feeley, P. Marks, F.B. Keane and W.A. Tanner, *Department of Surgery, Meath Hospital, and Trinity College, Dublin, Ireland*

Sepsis remains the cause of considerable mortality despite the use of powerful antibiotics. Many potent antiseptic agents have been developed but hitherto none was suitable for systemic administration. Taurolidine is a new antiseptic suitable for intravenous administration. Having previously reported the potent anti-endotoxin effects of taurolidine in the jaundiced rat we have, in this study, assessed the effects of taurolidine in a septic rat model.

Sixty male rats were subjected to laparotomy, and peritonitis was induced by double puncture of the ligated caecum using an 18 gauge needle. Animals were randomly divided into treatment and control groups and were given either taurolidine 100 mg/kg or an equal volume of saline, intravenously, at 6 h and 12 h after laparotomy.

In the control group 16 (53 per cent) animals were dead 24 h after laparotomy compared with two (7 per cent) in the treatment group ($P<0·0001$). At 48 h, 26 control and 17 treatment animals were dead ($P<0·01$). No animals died during the following 24 h in either group. Overall survival in the taurolidine group was significantly greater than in controls ($P<0·01$).

We conclude that taurolidine is an effective antiseptic in the treatment of established peritonitis in this animal model.

Bipolar electrocoagulation: short or long blasts?

J.D. Harrison and D.L. Morris, *Department of Surgery, Queen's Medical Centre, Nottingham, UK*

The current view regarding bipolar diathermy electrocoagulation is that after short periods of time (around 2 s) the electrical properties of the tissue change, rendering further coagulation ineffective. To test this theory we used the fresh iliac arteries and aortas of lagomorphs, which were excised *in vivo*. The diameter of the vessels was measured with a micrometer, and the experiments were carried out in two groups: those vessels 2–3 mm in diameter, and those 4–5 mm. The vessels were subjected to either 2 or 20 s of electrocoagulation with a BICAP probe and generator at a fixed power setting, using a fixed weight of 500 g applied to the probe head. The bursting pressure of the coagulated vessel wall was determined by cannulating the vessel and gradually increasing the distending pressure (measured with an electronic transducer) until the coagulum seal fractured.

Vessel size (mm)	Time (s)	Pressure (cm) median (range)	Mann–Whitney *U* test	*P*
2–3	2	460 (100–1120)		
($n=22$)	20	760 (360–1140)	158·5	0·038
4–5	2	400 (100–640)		
($n=14$)	20	800 (400–1120)	72	0·015

These data oppose the widely held view that prolonged bipolar diathermy is unproductive, and suggest that more effective haemostasis of bleeding vessels may be achieved by more prolonged use of the diathermy probe.

Is perioperative analgesia important in the genesis of postoperative fatigue?

M.R. Zeiderman, E. Welchew and R.G. Clark, *University Department of Surgery and Department of Anaesthetics, Northern General Hospital, Sheffield, UK*

Persistent tiredness after surgery is common and appears to be related to the magnitude of the operative procedure[1]. Epidural analgesia influences postoperative cardiorespiratory function and reduces the catabolic response to abdominal surgery[2]. This study has examined whether epidural analgesia has a therapeutic role in limiting the development of postoperative fatigue.

Twelve patients admitted for elective abdominal surgery were randomized to receive postoperative analgesia with intermittent intramuscular morphine ($n=6$; four women, two men, age range 27–71 years, median 53 years) or a continuous infusion of epidural fentanyl ($n=6$; three women, three men, age range 27–68 years, median 52 years). Fatigue was assessed on an analogue scale of 1 (fit) to 10 (fatigued). Steady-state measurements of respiratory gas exchange, respiratory rate (f_R) and tidal volume (V_T) were made before operation and repeated on the third postoperative day. Resting energy expenditure (REE) was calculated from Weir's formula.

	Fatigue (units)		REE (kJ day^{-1})		f_R (breaths min^{-1})		V_T (litres)	
	E	NE	E	NE	E	NE	E	NE
Preop	2·5 ± 0·4	2·5 ± 0·4	7223 ± 1162	6679 ± 844	11 ± 1	16 ± 2	0·58 ± 0·09	0·42 ± 0·03
P	<0·001	<0·001	n.s.	n.s.	<0·02	n.s.	n.s.	n.s.
Postop	8·8 ± 0·7	5·8 ± 0·7	6922 ± 1404	6738 ± 301	18 ± 2	18 ± 2	0·44 ± 0·07	0·46 ± 0·04

All results are given as mean ± s.e.m.: Mann–Whitney *U*
E, epidural; NE, non-epidural

Epidural analgesia does not confer any added advantage over intramuscular opiates in limiting the development of postoperative fatigue.

Can the energy requirements of burned patients be accurately predicted?

J.K.G. Laitung and J.A.D Settle (introduced by M J. McMahon), *Yorkshire Regional Burns Centre, Pinderfields Hospital, Wakefield, UK*

Calculation of energy requirement from formulae based on body weight and size of burn[1,2] is known to overestimate measured energy expenditure in burned patients[3] The aim of this study was to measure energy expenditure in burned patients and derive an equation to give actual energy requirement from clinical data.

Resting energy expenditure (REE) was measured by indirect calorimetry in 20 patients aged 20–81 (mean 37) years. Their total burn size was 20–65 per cent (mean 35 per cent) and the size of full-thickness burns (per cent FT) 0–60 per cent (mean 15 per cent). Stepwise regression analysis of these and other clinical variables was performed to calculate the best fit prediction of percentage increase in REE above that of the value obtained by the Harris–Benedict formula for normal individuals This yielded the equation

$$32+(0{\cdot}3\times\%\text{FT burn})-(0{\cdot}4\times\text{days after burn})+34\ (\text{if septic})$$

Validation of this formula was carried out in a further 15 patients aged 4–81 years (mean 27 years) with total burn size 8–48 per cent (mean 26 per cent) and full-thickness burn size 0–38 per cent (mean 8 per cent). This showed good correlation between calculated energy expenditure and measured energy expenditure ($r=0{\cdot}83$, $P<0{\cdot}0001$)

	REE (calculated)	REE (measured)
Mean ± s e m	1852 ± 58	1815 ± 61 (kcal/day)

In burned patients, REE can therefore be calculated from clinical data which enables nutritional requirement to be supplied precisely without the use of a calorimeter.

Risks of an intracranial haematoma in head-injured adults and children

G. Teasdale, G. Murray, E Anderson and D Mendelow, *Institute of Neurological Sciences, Glasgow, UK*

Knowing the risks of developing an intracranial haematoma for different groups of head-injured patients can lead to earlier detection, improved outcome and more efficient management. We have therefore extended, to children, previous work that identified the importance of a skull fracture in adults[1], and in both groups have also determined the importance of alteration in consciousness Data on these findings were determined in a retrospective series of 1107 patients with traumatic intracranial haematoma admitted from an Accident and Emergency Department (A and E) to a regional neurosurgical unit. Data about the total population at risk were obtained from surveys involving 8406 patients The table shows the occurrence of skull fracture and of altered consciousness in the two groups and the corresponding risk of developing haematoma calculated from the total numbers at risk, using either the method described by Mendelow *et al* [1] or, when multiple factors are considered, by global linear modelling

	Haematomas (%)		A and E sample (%)		Absolute risk	
	Adults	Children	Adults	Children	Adults	Children
No skull fracture						
Fully conscious	4	16	92	95	7900	13 000
Altered consciousness	10	12	5	3	180	580
Coma	8	10	1	3	27	65
Skull fracture						
Fully conscious	10	18	1	1	45	160
Altered consciousness	29	19	1	0·2	5	25
Coma	38	24	1	0·1	4	12

Although children are at less risk than adults, in both groups the presence of a skull fracture is an important indication of the risk of subsequent intracranial haematoma.

1 Mendelow AD, Teasdale G, Jennett B *et al* Risks of intracranial haematoma in head injured adults *Br Med J* 1983; **287**. 1173–6

A new method of quantifying median cerebral cortical transit times

A.R. Naylor, J.M. Slattery, A Notghi, J.D. Miller and M.V. Merrick, *Departments of Clinical Surgery, Clinical Neurosciences and Nuclear Medicine, The Royal Infirmary and Western General Hospitals, Edinburgh, UK*

A new method for quantifying regional median cerebral cortical transit time (MCTT), which corrects for the error due to dispersion of the bolus following intravenous injection of pertechnetate, was validated against middle cerebral artery velocities measured using transcranial Doppler ultrasound Reproducibility (of 3 studies) and the response to hyperventilation and rebreathing were studied in 13 normal volunteers (aged 25–54 years).

Both techniques were reproducible, with the coefficients of variation being 5·7 per cent for MCTT and 6·3 per cent and 6·8 per cent for peak and mean velocity respectively There was a linear relationship between end-tidal CO_2 (ET_{CO_2}), and MCTT ($r=0{\cdot}84$, gradient $=-1{\cdot}47$ per 1 per cent change in ET_{CO_2}), peak velocity ($r=0{\cdot}81$, gradient $=15{\cdot}5$ cm/s per 1 per cent change in ET_{CO_2}) and mean velocity ($r=0{\cdot}86$, gradient $=13{\cdot}6$ cm/s per 1 per cent change in ET_{CO_2}) There was no significant difference in slope gradients between individuals, and the wide range of normal MCTT for a given end-tidal CO_2 was caused by interindividual variation. The mean interhemispheric MCTT difference was $0{\cdot}25\pm0{\cdot}22$ s A previously unconfirmed relationship between velocity and MCTT was demonstrated· under normal physiological conditions, peak velocity was proportional to the inverse of hemispheric MCTT, which in turn represents the ratio of blood flow to blood volume

Hypoxia and hypotension during colonoscopy and endoscopy

J.F. Lancaster, D.C Bartolo and D J. Leaper, *Department of Surgery, University of Bristol, UK*

Cardiac arrhythmias and hypoxia have been described in 30 per cent of endoscopies and account for 60 per cent of deaths We have performed studies to determine whether cardiopulmonary disturbance is also a feature of large bowel fibreoptic examination and whether such changes are predictable

Sixty patients undergoing endoscopy ($n=30$) and colonoscopy ($n=30$) had continuous monitoring of arterial oxygen saturation (S_{a,O_2}), pulse and mean blood pressure (BP) The degree of patient distress, duration, dose of sedative and details of the endoscope and operator were recorded.

Marked hypotensive (>40 per cent fall BP) and hypoxic (>8 per cent fall S_{a,O_2}) changes occurred in 13 per cent and 16 per cent of the group respectively There were no significant differences in fall in BP, S_{a,O_2} or pulse between the endoscopy and colonoscopy groups The dose of sedative was significantly related to the fall in S_{a,O_2} ($P<0{\cdot}001$) but not to the fall in BP Falls in S_{a,O_2} and BP were both related to the duration of the procedure ($P=0{\cdot}01$). There were no correlations between the degree of hypoxia or hypotension and the patient's age or previous medical history

Hypotension and hypoxia occur in both colonoscopy and endoscopy and are neither predictable nor usually recognizable clinically We recommend pulse, oximetric and BP monitoring throughout gastrointestinal endoscopy for maximal patient safety

Breath-hydrogen testing: an indicator of small bowel overgrowth following pouch formation

W.A. Kmiot, J.D. O'Brien and M.R.B Keighley, *The General Hospital, Birmingham, UK*

The absolute number of bacteria per gram of ileal chyme and the anaerobic to aerobic ratio increase after ileal reservoir construction. The production of hydrogen by anaerobic fermentation is a recognized measure of small intestinal bacterial overgrowth

After restorative proctocolectomy 30 patients performed a series of breath-hydrogen estimations at 5-min intervals for 1 h A further 30, matched for age and sex, were tested as controls. All subjects fasted for a minimum of 20 h

Patients with ileal reservoirs had a higher mean fasting breath-hydrogen value than control subjects (16·4 *versus* 5·7 parts per million (p.p.m.), $P < 0{\cdot}05$) Six 'pouch' patients did not exhibit a rise in breath hydrogen either on repeated tests or on instillation of isotonic glucose directly into the pouch These patients had significantly lower faecal bacterial counts (2×10^6) than the remaining 24 patients who exhibited rises in breath hydrogen of at least 20 p.p.m (faecal count 9×10^6, $P < 0{\cdot}02$) All patients with a fasting breath-hydrogen level of >10 p.p.m. had anaerobic bacterial pouch overgrowth ($>10^7$ colony forming units per gram), compared with none of the remainder ($P < 0{\cdot}05$) There was no relationship between pouch overgrowth and the frequency of defaecation This study confirms that fasting non-invasive breath-hydrogen sampling acts as a sensitive indicator of ileal bacterial overgrowth following pouch formation.

Relationship between bile acid malabsorption using ^{75}SeHCAT scanning method and diarrhoea following right hemicolectomy: evidence for intestinal adaptation

A.J. Jewkes, C.W.O. Windsor, R.S. Ward and A.E. Timmins (introduced by J. Neoptolemos), *Departments of Surgery and Nuclear Medicine, Royal Infirmary, Worcester, UK*

Diarrhoea following right hemicolectomy occurs in up to 50 per cent of patients[1] Malabsorption of bile acids due to resection of the terminal ileum is thought to be important in the pathogenesis of these post-operative symptoms, but has been inadequately studied

In a prospective study, the bile acid pool was examined using 7-day ^{75}SeHCAT scanning in 21 patients in order to evaluate the temporal relationship between bile acid malabsorption and diarrhoea following right hemicolectomy[2]. Patients were imaged preoperatively and in the early (2–11 weeks) and late (44–80 weeks) postoperative periods Stool frequency was also recorded at the time of each scan.

The median preoperative ^{75}SeHCAT retention ratio was 44·3 per cent (range 17–73 per cent, normal value >19 per cent) compared with the significantly lower early postoperative values (3·5 per cent; 0–15 per cent) and the late postoperative values (3·0 per cent; 0–14·5 per cent) (both $P < 0{\cdot}001$; two-tailed Mann–Whitney *U* test). In the early postoperative period 10 out of 21 (48 per cent) patients had diarrhoea (median stool frequency 4/day, range 0·5–10/day) compared with only 3 out of 18 (17 per cent) in the late postoperative period (2/day, 0·33–6/day) ($P = 0{\cdot}013$) The correlation between the length of small bowel resected and the degree of diarrhoea was not significant in either the early ($r = 0{\cdot}17$) or late ($r = 0{\cdot}21$) postoperative periods. There was also no significant correlation between the degree of diarrhoea and bile acid malabsorption (early $r = 0{\cdot}13$ and late $r = 0{\cdot}05$).

These original findings suggest that despite continuing bile acid malabsorption, intestinal adaptation occurs, resulting in a significant reduction in stool frequency, the mechanisms require elucidation

Is intractable constipation associated with a systemic autonomic neuropathy?

D.J Waldron, N.S. Williams, D. Kumar, R.I. Hallan and M. Swash*, *Departments of Surgery and *Neurology, The London Hospital, London, UK*

Patients with intractable constipation often have symptoms suggesting a multisystem disorder Do they have a systemic disturbance of autonomic nerve function? Eight patients with intractable constipation and six controls underwent assessments of autonomic cardiovascular reflexes – fall in systolic blood pressure on standing (SBPS), ratio of heart rate between the 30th and 15th beat after standing (RHRS), variation in heart rate with deep breathing (VHRB) and ratio of the slowest heart rate following to the fastest rate during a Valsalva manoeuvre (RHRV) Results were compared with conventional normal ranges (CNR).

SBPS pressure did not differ between controls and constipated patients ($8{\cdot}3 \pm 2{\cdot}1$ *versus* $9{\cdot}2 \pm 2{\cdot}4$ mmHg, $P > 0{\cdot}5$, CNR being <30 mmHg) VHRB was $27{\cdot}6 \pm 6{\cdot}5$ in controls *versus* $21{\cdot}5 \pm 2{\cdot}8$ in constipated patients ($P > 0{\cdot}4$), none being less than the CNR of >10 While there was a significant difference during RHRV ($1{\cdot}9 \pm 0{\cdot}1$ for controls *versus* $1{\cdot}4 \pm 0{\cdot}1$ in constipated patients, $P < 0{\cdot}02$), this was only in degree of normality as indicated by a CNR ratio >1·1 No significant difference in RHRS was seen ($1{\cdot}03 \pm 0{\cdot}01$ for controls *versus* $0{\cdot}97 \pm 0{\cdot}04$ in constipated patients, $P > 0{\cdot}2$), but four of eight patients as opposed to one of six controls had ratios outside the CNR of 1·0.

Half the constipated group had an abnormality of one test of autonomic nerve function Generalized autonomic neuropathy may thus be an aetiological factor in a subgroup of patients with intractable constipation.

Prognostic value of nucleolar organizer regions and ploidy status in advanced colorectal cancer

K. Moran, T. Cooke, G. Forster, P. Gillen, S Sheehan, P. Dervan and J M. Fitzpatrick, *Departments of Surgery and Pathology, Mater Hospital, Dublin, and Royal Liverpool Hospital, UK*

Conventional clinical and pathological prognostic parameters are inaccurate in colorectal cancer One third of patients with Dukes' B carcinoma die while one third of those with Dukes' C survive long term, irrespective of histological differentiation[1,2]. We studied the prognostic value of nucleolar organizer regions (NORs) and ploidy status and their correlation with established prognostic parameters in advanced colorectal cancer Fifty-one patients aged 35–81 years (mean 61·6 years) with Dukes' C tumours (eight with liver metastases) were studied All were followed for a minimum of 5 years. Sections from primary tumours and lymph node metastases (LN) were stained for NORs Ploidy status was determined for primary tumours in 40 patients using flow cytometry. NOR and ploidy status were correlated with age, sex, histological differentiation, presence of liver metastases and survival time, and the independent significance of prognostic variables was determined using Cox's multivariate regression analysis. NORs and ploidy values did not correlate with age or sex. Sixteen patients who survived 5 years had lower NOR counts than non-survivors ($P < 0{\cdot}05$; Mann–Whitney *U* test) Survivors had a lower percentage of aneuploid tumours. NORs were the most important individual variable for predicting survival ($P < 0{\cdot}05$). Ploidy values correlated with histological differentiation and liver metastases.

	Survivors		Non-survivors	
	Primary	LN	Primary	LN
NOR, median (range)	12 (8–15)	11 (8–15)	17 (14–25)	18 (13–25)
Ploidy (percentage aneuploid)	40		57	

We concluded that NORs were more accurate and ploidy values were as accurate as conventional clinical and pathological parameters in predicting 5-year survival in advanced colorectal cancer

1. Jones D, Moore M, Schofield P Prognostic significance of DNA ploidy in colorectal cancer a prospective flow cytometric study. *Br J Surg* 1988, **75**: 28–33.
2. Banner B, Tomas-De-La Vega J, Roseman D, Coon J. Should flow cytometric DNA analysis precede definitive surgery for colon carcinoma? *Ann Surg* 1985, **202**. 740–4

Growth autonomy and invasiveness in vitro of human colorectal carcinoma cells

N. Williams, J. Daly and M. Herlyn (introduced by D. Bouchier-Hayes), *The Wistar Institute of Anatomy and Biology and the Department of Surgery, University of Pennsylvania, Philadelphia, USA*

Growth autonomy and invasion play important roles in the progression of colorectal carcinoma to the metastatic stage. Growth autonomy *in vitro* is defined as the ability of cells to survive and proliferate in the absence of exogenously added growth factors In this study, five colorectal carcinoma cell lines were adapted over a 4-month period to growth in medium W487 without growth factors and other proteins, and examined for changes in expression of tumour-associated antigens and in invasiveness through a reconstructed basement membrane (Matrigel) Antigen expression on carcinoma cells was determined by a fluorescent analysis cell sorter using a panel of monoclonal antibodies Invasiveness *in vitro* was measured as the ability of cells to invade a reconstructed basement membrane in the Boyden chamber chemoinvasion assay In each of these experiments, the cell line adapted to grow in protein-free medium was compared with the parent cell line which was maintained in W487 medium supplemented with exogenous growth factors and 2 per cent fetal calf serum (FCS) There were no significant differences in tumour-associated antigen expression between the adapted cell lines and the parental cell lines. The results of the invasion assays (mean ±s.d.) are expressed as the number of cells per high power field (HPF) that migrate through the basement membrane.

	Number of cells/HPF				
W487 medium	SW 403	SW 1116	SW 48	SW 948	NWG 1
With FCS	5·7±3·1	1·1±0·8	4·2±3·2	3·0±1·9	5·8±1·7
Protein-free	23·0±3·7*	19·1±3·7*	12·5±5·9*	1·5±1·1	3·6±1·6
Fold increase	4·0	17·4	3·0	—	—

* $P<0{\cdot}001$

The data show that in three of the five cell lines tested there was a significant increase in invasiveness in the cells adapted to protein-free medium when compared with the parental cell line. These results suggest that the acquisition of growth autonomy can increase the invasive capacity of colorectal carcinoma cells *in vitro*.

Monoclonal antibody detection of fibrinolytic activation during salvage autotransfusion

J.F. Thompson, the late P.C. Clifford, J.H.H. Webster and A.D.B. Chant, *Vascular Unit, Royal South Hampshire Hospital, Southampton, UK*

Reinfusion of activated clotting factors during salvage autotransfusion may theoretically lead to coagulopathy. To investigate this possiblity 17 patients have been studied undergoing autotransfusion (non-washed) during elective aortic surgery. Maintenance of adequate intraoperative heparinization was judged by activated clotting time measurements and confirmed by postoperative chromogenic activated factor X assay.

Fibrinolytic activity was measured using immunoagglutination based on a monoclonal antibody directed against fibrin-split products (XDP)[1]. Plasma XDP levels were determined in paired samples from autotransfusion reservoirs, from patients preoperatively, and at 0 h, 4 h and 24 h postoperatively.

Normal XDP (200 ng/ml) was found in all 17 patients preoperatively, while 28 of 32 reservoirs had raised XDP (mean 3770 ng/ml· range 400–24 000). XDP levels were raised in four recipients' plasma immediately postoperatively but did not exceed 500 ng/ml. There was no clinical or other haematological evidence of disseminated intravascular coagulopathy after salvage autotransfusion.

Plasmin activation and subsequent fibrin degradation occurs within reservoirs during autotransfusion, despite high-dose heparinization. However, reinfusion of non-washed blood did not lead to significant activation of fibrinolysis in the patients studied.

The influence of platelet and leucocyte depletion on pulmonary microembolization during major surgery

D.B. Hocken, D.A.J. Galvin, C.M. Backhouse, R.A Harper and C.N. McCollum, *Department of Surgery, Charing Cross and Westminster Medical School, London, UK*

Platelet and leucocyte microembolization may lead to pulmonary dysfunction after major surgery. A study was therefore carried out to see whether selective preoperative depletion of these cells would reduce pulmonary damage.

Twenty pigs were randomized to selective cell separation (SCS) (Haemonetics V-50 cell separator) or control. Animals underwent standardized aortic surgery consisting of midline laparotomy, and 90-min aortic occlusion. After aortic declamping the animals became hypotensive for 60 min before full resuscitation. Vena caval microaggregate levels were assessed by screen filtration pressure (SFP). Pulmonary vascular resistance (PVR), arterial P_{O_2} (P_{a,O_2}) and alveolar–arterial P_{O_2} difference ($P_{A\text{-}a,O_2}$) were recorded.

	Fall in platelets (×10⁹/l)	Rise in SFP (slope)	Rise in PVR (d-s/cm⁵)	Rise in P_{A-a,O_2} (mmHg)	Fall in P_{a,O_2} (mmHg)
Control	216±43	1·21±0·2	917±76	24·2±2·7	20·8±1·9
SCS	76±25*	0·78±0·2*	380±54*	14·8±3·1*	11·3±1·7*

All results are mean±s.e.m. * $P<0{\cdot}01$, Mann–Whitney *U* test

Cell separation reduced initial mean platelet and leucocyte counts by 75 per cent and 30 per cent respectively ($P<0{\cdot}001$). In control animals there was a significant fall in platelet count during surgery which was reduced by cell separation, whilst at the same time there was a rise in SFP which was inhibited in cell-separated animals. When the cross-clamp was released, PVR rose considerably in controls compared with cell-separated animals. This was associated with an improvement in postoperative pulmonary function in cell-separated animals ($P_{A\text{-}a,O_2}$, P_{a,O_2}).

Selective cell separation prevented recruitment of platelets and leucocytes into microemboli, reduced a rise in PVR and improved postoperative pulmonary function.

Calf pump failure and fibrinolysis

H. Gajraj and N.L. Browse, *Department of Surgery, St Thomas' Hospital Medical School, London, UK*

Venous ulceration is associated with calf pump failure, reduced blood fibrinolytic activity and pericapillary fibrin cuffs (which are thought to block oxygen diffusion) in affected skin[1]. This study investigates the relationship between local tissue fibrinolysis and transcutaneous oxygen tensions (P_{tc,O_2}).

^{125}I-fibrin clots, formed by the injection of 0·05 ml of ^{125}I-labelled fibrinogen and thrombin, were produced in the subcutaneous tissue of the legs of 33 subjects with healed venous ulcers, 10 subjects with bilateral varicose veins and the normal skin of 11 controls. The clearance half-life of the fibrin ($^{125}F_{\frac{1}{2}}$) was calculated for each site. Calf pump function was assessed by foot volumetry, measuring the relative expelled volume (EV_{rel}) and the half-volume refilling time ($TV_{\frac{1}{2}}$). The P_{tc,O_2} of the 'gaiter' skin was measured with a Clarke-type electrode (Radiometer).

	Results (mean and s.d.)	
	$^{125}F_{\frac{1}{2}}$ (h)	P_{tc,O_2} (mmHg)
Controls	18·2 (5·1)	70·6 (7·6)
Subjects with varicose veins	24·7 (6·5)*	75·9 (20·6)†
Subjects with healed ulcers		
Never-ulcerated leg	25·1 (8·9)**	58·3 (17·3)**
Healed leg	36·9 (21·1)***	48·7 (17·4)***

Compared with controls. † not significant, * $P<0{\cdot}05$, ** $P<0{\cdot}01$, *** $P<0{\cdot}001$ (Mann–Whitney *U* test)

Significant negative correlations were found between $^{125}F_{\frac{1}{2}}$ and the P_{tc,O_2} ($P<0{\cdot}01$) and between $^{125}F_{\frac{1}{2}}$ and the $TV_{\frac{1}{2}}$ ($P<0{\cdot}01$). Local interstitial fibrinolysis appears to be related to transcutaneous oxygen tensions and calf pump function.

The significance of plasma fibrinolytic activity in the development of ulceration in patients with chronic venous insufficiency

S.A. Whawell, T Harbourne, S. Vasdekis, D. Christopoulos, H Clark and A.N. Nicolaides, *Irvine Laboratory for Cardiovascular Investigation and Research, Academic Surgical Unit, St. Mary's Hospital Medical School, London, UK*

It has been suggested that fibrinolytic activity may be an important factor in the development of skin changes and ulceration in limbs with chronic venous hyptertension[1]. Thirty-seven patients with chronic venous problems (varicose veins, liposclerosis and ulceration) have been studied using ambulatory venous pressure (AVP) measurements and euglobulin lysis time[2] corrected to a standard (3 g/l) plasma fibrinogen concentration (ELTc).

Eighteen of the 37 patients had skin changes. four had liposclerosis only and 14 had both liposclerosis and ulceration.

AVP was less than 35 mmHg (normal) in eight patients, none of whom had any skin changes; it was greater than 65 mmHg (severe) in seven patients, six of whom had ulceration, and between 35 and 65 mmHg (moderate) in 22 patients In this moderate group ELTc was less than 240 min in 12 patients of whom two had liposclerosis only, and greater than 240 min in 10 patients of whom nine had liposclerosis and seven had both liposclerosis and ulceration (Fisher's exact test, $P<0·001$)

The results suggest that although venous hypertension is a factor responsible for skin changes, fibrinolytic activity measured by the ELTc is also a major factor which determines whether skin changes will occur in patients with moderate venous hypertension

Quantitative assessment of venous outflow resistance in the postphlebitic limb

A. Rulo, G. Belcaro and A.N. Nicolaides, *Irvine Laboratory for Cardiovascular Investigation and Research, Adacemic Surgical Unit and Vascular Unit, St. Mary's Hospital Medical School, London, UK*

Venography is the traditional method used to diagnose venous obstruction The purpose of this study was to develop a method for the measurement of venous outflow resistance. Venous occlusion air-plethysmography has been used to measure absolute volume and flow (Q) changes[1] with simultaneous measurement of venous pressure (P) on the release of a thigh cuff inflated to 70 mmHg. Resistance ($R=P/Q$) was calculated at intervals of 0·4 s (in mmHg l^{-1} min^{-1}) during venous emptying. It was compared with a previously described method of evaluation of venous obstruction which measured the arm/foot pressure differential (ΔP) in the supine subject[2].

The results of 10 normal limbs and 18 limbs with venographic obstruction (10 with $\Delta P>5$ mmHg and 8 with a $\Delta P<5$ mmHg) are shown in the table.

	Venous resistance mean ± s d. (mmHg l^{-1} min^{-1})		
		Patients	
Venous pressure	Normal volunteers	$\Delta P<5$ mmHg	$\Delta P>5$ mmHg
15 mmHg	10·3 ± 2·0	18·5 ± 10·4	43·8 ± 10·7
25 mmHg	8·3 ± 1·3	14·0 ± 6·5	31·7 ± 15·9
35 mmHg	8·0 ± 1·3	14·2 ± 6·8	22·2 ± 5·0

Limbs with a $\Delta P>5$ mmHg had a markedly elevated resistance (no overlap with normal volunteers). Patients with $\Delta P<5$ mmHg were in the normal range with the exception of three occupying an intermediate position These results suggest that venous resistance is not constant, but varies with pressure. It should be used as a 'gold standard' to evaluate non-invasive tests and study the natural history of patients with outflow obstruction

Long-term effect of elastic compression on venous haemodynamics of the leg

D. Christopoulos and A.N. Nicolaides, *Irvine Laboratory for Cardiovascular Investigation and Research, Academic Surgical Unit and Vascular Unit, St. Mary's Hospital Medical School, London, UK*

Although elastic compression stockings produce symptomatic relief, their haemodynamic effects are unknown Air-plethysmography has been used to measure venous volume (VV), venous filling index (VFI), which is a measure of venous reflux, ejection fraction (EF) of the calf muscle pump as a result of one tip-toe movement and the residual volume fraction (RVF) after 10 tip-toe movements[1] Twenty normal limbs and 20 limbs with primary varicose veins (PVV) have been studied Deep venous disease had been excluded by venography, duplex scanning and ambulatory venous pressure (AVP) measurements.

Subsequently, graduated medium compression stockings (30 mmHg at the ankle, 15 mmHg at the calf, 8 mmHg at the thigh) were worn by the patients with PVV for 4 weeks. At the end of this period air-plethysmography and AVP measurements were repeated with the stockings off The results of the measurements (median and 90 per cent range) and the mean percentage change as a result of long-term elastic compression are shown in the *Table.*

Limbs	AVP (mmHg)	VV (ml)	VFI (ml/s)	EF (%)	RVF (%)
Normal		112 (80–150)	1·1 (0·6–1·6)	75 (60–85)	15 (1–30)
PVV before stocking	43 (6–55)	165 (75–331)	6·0 (1·6–15)	54 (38–82)	49 (15–57)
PVV after stocking	33 (6–47)*	156 (76–280)*	4·2 (1·5–12)*	61 (49–86)*	36 (6–49)*
Percentage change	−16	−5·5	−15	+21	−27

* $P<0·01$, Wilcoxon test for paired samples

The results indicate that elastic compression produces a long-term haemodynamic benefit The decrease in AVP is the result of reduction in venous reflux and an increased ejecting capacity of the calf muscle pump.

Splenic reticuloendothelial function following surgery

M.C. Aldridge, S. Cheslyn-Curtis, S.J.D. Chadwick and H.A F. Dudley, *Academic Surgical Unit, St. Mary's Hospital, London, UK*

Although the spleen is a major component of the reticuloendothelial system, with an important role in filtering blood-borne particles, the effects of surgery on splenic function or on resistance to Gram-negative infection are incompletely understood.

Kupffer cell extraction of technetium tin colloid (TTC) was measured in preoperative (group A; $n=20$) and postoperative patients (11 uncomplicated, group B; nine critically ill, group C). Eight (two group B, six group C) had also undergone splenectomy $T_{\frac{1}{2}}$ blood clearance (min; mean ± s.e.m.) was 1·47 ± 0·08 (group A), 2·22 ± 0·21 (group B) ($P<0·01$), 2·46 ± 0·18 (group C) ($P<0·001$).

The effect of splenectomy on the clearance kinetics of TTC and of ^{75}Se-labelled *Escherichia coli* was also studied in rabbits 1 month after either sham laparotomy or splenectomy (see *Table*).

	Sham laparotomy ($n=6$)	Splenectomy ($n=7$)
$T_{\frac{1}{2}}$ TTC (min)	0·69 ± 0·07	1·01 ± 0·06*
$T_{\frac{1}{2}}$ *E. coli* (min)	0·68 ± 0·02	1·12 ± 0·11*
Uptake as percentage of injected dose/g of tissue		
Liver uptake (TTC)	0·70 ± 0·07	0·51 ± 0·02*
Liver uptake (*E coli*)	0·65 ± 0·06	0·49 ± 0·03*
Lung uptake (TTC)	0·23 ± 0·10	0·51 ± 0·14*
Lung uptake (*E coli*)	0·23 ± 0·04	0·40 ± 0·08*

Data are mean ± s.e.m., * $P<0·05$ (Mann–Whitney U test)

These results suggest that there is impairment of reticuloendothelial function after surgery which can be detected in patients by delayed clearance of TTC, and that splenectomy reduces Kupffer cell uptake of both TTC and *E. coli* with a consequent increase in pulmonary localization We conclude that the spleen is important for normal Kupffer cell clearance of particulate matter following surgery, thus supporting the concept of splenic preservation.

Lymphocyte traffic in rat small bowel transplants

P.A. Lear, A. Cunningham, P.W. Crane and R.F.M. Wood, *Department of Surgery, St. Bartholomew's Hospital, London, UK*

Small bowel transplants incite not only a vigorous rejection response but also induce graft-versus-host disease. To elucidate these phenomena, the lymphocyte traffic of host and donor origin has been discretely monitored in unimmunosuppressed (control) and cyclosporin-treated (15 mg kg^{-1} day^{-1} for 7 days) DA recipients of PVG intestinal transplants. PVG small bowel grafts are rejected in 6–8 days by untreated DA hosts but survive more than 50 days after cyclosporin therapy. Unimmunosuppressed rats were killed on days 1 to 6, cyclosporin-treated rats on days 7, 14, 21 and 28. All host lymphoid tissues and grafts were harvested and stained with strain-specific monoclonal antibodies to identify cells of host and graft origin (MN4 – anti-class 1 DA; OX27—anti-class 1 PVG).

When graft infiltration was assessed in control animals, host lymphocytes were found particularly in the Peyer's patches on day 1. Later there was progressive infiltration of the lamina propria and finally the epithelium, which was mostly destroyed by day 6. In cyclosporin-treated animals, the architecture of the gut remained normal throughout, except the Peyer's patches which were replaced by simple accumulations of host lymphocytes. Epithelial lymphocytes were also of host origin.

Assessment of host infiltration showed that in control animals all host lymphoid tissues contained graft-derived cells from day 1. The number of cells increased until day 4 after which they disappeared, presumably destroyed. In contrast, on day 7, cyclosporin-treated rats had very large numbers (5–10 times that of controls) of graft-derived cells in all lymphoid compartments. They increased further on day 14, but were absent from all areas except the thymus by day 28. These studies demonstrate the true traffic of 'passenger leucocytes', and give some insight into the origins of graft-versus-host disease.

Pulsatility of insulin and glucagon secretion from intraportal and intrasplenic islet autografts in Cynomolgus macaques

R. Sutton, D.R. Matthews, M. Burnett, D.W.R. Gray, R.C. Turner and P.J. Morris, *Nuffield Department of Surgery and Diabetes Research Laboratories, Oxford University, Oxford, UK*

Both insulin and glucagon are normally secreted in a regularly pulsatile manner, maximizing the efficiency of normal glucose homeostasis, however, the pancreatic endocrine pacemaker remains unidentified[1]. Pulsatility of insulin and glucagon release were examined in 11 normal animals and six animals after total pancreatectomy and subsequent islet autotransplantation. Fasting blood samples were taken at 2-minute intervals over 1 h, and plasma glucose, insulin and glucagon were determined. Time series analysis was performed by autocorrelation with Fisher's Z transformation, and by Fourier transform analysis.

Significant positive insulin peaks were present on autocorrelation of data from four normal animals, three out of four animals with well-maintained graft function (two intraportal and one intrasplenic), and neither of two animals with late graft failure. Pooled data from normal animals showed peak oscillatory activity at 14 min, pooled data from transplanted animals showed peak oscillatory activity at 24 min on autocorrelation ($r = 0.251$, $P < 0.05$), although there was no unified peak on Fourier analysis.

These data suggest that pulsatile hormone release may occur from an islet graft, and may contribute to more efficient glucose homeostasis. In addition, the pancreatic neural network would appear more likely to modulate than initiate pulsatile islet hormone secretion.

An objective approach to maintenance therapy in renal transplantation

C.S. Ubhi, F.T. Lam, A.I.D. Mavor and G.R. Giles, *Department of Surgery, St. James's University Hospital, Leeds, UK*

Renal allograft recipients immunosuppressed with cyclosporin alone who are likely to require additional maintenance therapy may be identified by fine needle aspiration cytology (FNAC)[1]. In this prospective study we question the benefits of earlier introduction of additional maintenance therapy and whether steroids could be avoided by FNAC monitoring.

Sixty-two recipients of cadaveric renal allografts were monitored by FNAC during the first 30 days after transplantation. Nineteen patients displayed no sign of rejection (group A), 24 patients had apparent resolution of rejection by intravenous methylprednisolone (group B), whereas 19 had evidence of continuing rejection (group C) after three doses of methylprednisolone. Group C patients were randomized to receive maintenance doses of either azathioprine or oral prednisolone.

Assessment at 3 months showed the median (range) of serum creatinine for groups A, B and C to be 139 (104–206), 148 (110–450) and 205 (83–324) μmol/l respectively. Eighteen of the 19 group A patients were rejection-free on cyclosporin alone. Only five group B patients have required oral prednisolone after further rejection episodes whereas seven group C patients commenced triple therapy. There were three graft losses in group C and two in group B ($P > 0.05$ Fisher's exact test).

We have demonstrated that FNAC provides an objective approach to maintenance immunosuppression in patients experiencing early rejection episodes and that oral steroids may be avoided in 65 per cent of patients.

Soluble interleukin 2 receptor levels in renal allograft dysfunction

J.L.R. Forsythe, B.K. Shenton, N.R. Parrott, R.M.R. Taylor and G. Proud, *Department of Surgery, University of Newcastle upon Tyne, UK*

T-lymphocyte activation is associated with increased expression of interleukin 2 receptor (IL-2r), both on the cell and in the free soluble form. The hypothesis that soluble IL-2r levels may rise during renal allograft rejection was tested.

Initially, IL-2r levels, as measured by an enzyme-linked immunosorbent assay, were determined in five normal volunteers and 10 renal transplant recipients (five with stable function and five suffering rejection). Levels in the three groups were significantly different.

	Normals	Stable	Rejection
Number of subjects	5	5	5
Median IL-2r level (units/ml)	244	960	1605
Significant difference from rejection (Mann–Whitney *U* test)	$P = 0.008$	$P = 0.03$	—

Daily plasma samples were then collected from renal allograft recipients in the first 14 days after transplantation. Out of 152 assays now performed, a plasma level over 1900 units/ml ($n = 18$), was always associated with rejection and a rise of over 400 units/ml in 24 h ($n = 6$) only occurred before a diagnosis of rejection. On no occasion was subsequently proved rejection seen in the face of low and stable IL-2r levels.

Plasma IL-2r levels do rise during allograft rejection and this fact may be of great diagnostic value in allograft dysfunction.

A clinical evaluation of a new preservation solution: phosphate-buffered sucrose

F.T. Lam, C.S. Ubhi, A.I.D. Mavor, J.P.A. Lodge and G.R. Giles, *Department of Surgery, St. James's University Hospital, Leeds, UK*

Short-term preservation of human kidneys is mainly conducted by perfusion with hyperosmolar citrate. This is associated with a relatively low primary function rate. We have tested an alternative solution in our clinical transplant programme. Kidneys from 18 consecutive donors were alternatively allocated to *in situ* aortic perfusion with hyperosmolar citrate or phosphate–buffered sucrose. The age, renal function, histocompatibility antigen match, and warm and cold ischaemic times proved similar in both groups. Twenty-five kidneys were transplanted locally and immunosuppression was initially by cyclosporin alone. The mean preservation time for both groups was 19 h.

Primary function was seen in nine kidneys (50 per cent) perfused with citrate and 15 (84 per cent) with sucrose ($P = 0{\cdot}037$ Fisher's exact test). A comparison between kidneys with primary function showed no significant difference in the 24-h urine output; however, the serum creatinine by the seventh day was significantly lower in the sucrose group ($P = 0{\cdot}029$ Mann–Whitney U test). Inulin clearance on day 1 was significantly better with sucrose ($P = 0{\cdot}01$ Mann–Whitney U test)

It is concluded that the use of phosphate-buffered sucrose is associated with a higher rate of primary graft function and an improved renal clearance.

Announcement

Reviews

The Editorial Board of *The British Journal of Surgery* continues to invite review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium of £100. Potential authors seeking advice on the suitability of review topics are advised to contact: Professor D. C. Carter, Regius Professor of Clinical Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK

Leading articles

The Editors invite submissions of signed leading articles to *The British Journal of Surgery*. These articles should be 600–1000 words in length, should address controversial topics of current interest and should be supported by key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium of £100 is payable on publication. Potential authors seeking advice on the suitability of topics are advised to contact: Professor D. C. Carter, Regius Professor of Clinical Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Surgical workshops

The Editors invite the submission of articles describing technical innovations or modifications which may be useful in surgical practice. These articles should be less than 500 words long; they can be accompanied by no more than two figures but should not carry supporting references. Articles submitted to the Surgical Workshop series may be subjected to external review and assessment by the Editorial Board before acceptance.

Case reports

The British Journal of Surgery receives an increasing number of case reports each year. Space within the Journal remains at a premium and the rejection rate is likely to be high. Authors are advised to restrict such reports to a maximum of 500 words, to use no more than five references and to submit no more than one illustration.

Correspondence

Early cholecystectomy after sphincterotomy for common duct lithiasis

Sir

We were very interested to read the article by Worthley and Toouli (*Br J Surg* 1988; **75**. 796–8), and Martin and Tweedle's letter (*Br J Surg* 1989, **76**: 101)

Worthley and Toouli state that gallbladder non-filling during endoscopic retrograde cholangiopancreatography (ERCP) is a predictive factor of biliary complications that justify cholecystectomy This idea seems to be disputed by Martin and Tweedle. We performed early and systematic cholecystectomy on elderly or very elderly surgical patients (over 75, average age 83 years) who had undergone sphincterotomy for common duct lithiasis[1].

We have therefore retrospectively assessed our current data 36 consecutive patients were treated in this way The ERCP, performed by the same practitioner, filled the gallbladder in 26 cases (group I) and did not fill it in nine cases (group II)

The percentage of acute cholecystitis (histological result given by the same laboratory) was 65 per cent (17 of 26 patients) for group I and 55 per cent (five of nine patients) for group II. No statistical difference was observed between the two groups

For our patients, gallbladder non-filling during ERCP is not a predictive factor of gallbladder problems.

For debate: cancer of the colon

Letter 1

Sir

We read Mr Marston's paper (*Br J Surg* 1989, **76** 71) with interest and, indeed, others have also considered a role for subtotal colectomy in the management of colon carcinoma[1] Many of Mr Marston's arguments make very good sense.

The more widespread use of the flexible sigmoidoscope suggests yet another alternative. When performing a left-sided resection, why not tailor it to leave about 60 cm of colon *in situ*, this length being accessible subsequently to the flexible instrument? The latter is more appropriate as a screening instrument than the colonoscope in that only simple patient preparation is required and it can be performed by the non-specialist in the outpatient department[2], all the more easily since the sigmoid colon and splenic flexure do not then present a problem.

Letter 2

Sir

I was interested to read Mr Marston's paper debating the case against total colectomy as a standard treatment for cancer of the colon (*Br J Surg* 1989; **76**. 71)

Mr Marston is, as always, stimulating and his arguments most plausible. His second point, however, states that there is ‘a high incidence of recurrent colonic cancer following partial colectomy because of synchronous or metachronous tumours . ’ When Sir Hugh Lockhart-Mummery and I reviewed the St. Mark's figures[1], we found that the actual incidence of metachronous cancer in those patients cured of one cancer was only 3·5 per cent with a lifelong follow-up Furthermore, the suggestion that removal of the entire mucosal field would eliminate the problem is not true because rectal carcinoma after colectomy is somewhat more common than a second colonic carcinoma and thus would still dictate a need for follow-up and sigmoidoscopy. Furthermore, there is no evidence that removal of the entire colon would eliminate suture-line recurrence which is most commonly because of extra visceral residues of the primary tumour or implantation of viable tumour cells Neither of these would be eliminated by total colectomy. Improvements in colonoscopic surveillance and polypectomy have further reduced the argument for total colectomy since the 1970s when our papers on the subject were written. We argued then that each primary cancer should be treated on its merits, that no colorectal cancer should be removed without proper visualization of the entire colon and rectum (to eliminate missed synchronous tumours), and that 3-yearly postoperative surveillance for life was probably worthwhile.

I believe that these arguments hold good today.

Facial paralysis due to a benign parotid tumour

Sir

We were interested to read the paper by Whillis, Goepel and Shorthouse (*Br J Surg* 1989; **76**. 95) reporting a case of a Warthin's tumour presenting with a parotid swelling and paresis of the ipsilateral facial nerve A review of the literature by the authors found only six cases of benign parotid tumours causing facial nerve paresis. Only one other case was due to a Warthin's tumour

We would suggest that this condition is more common than has been thought Two similar cases of benign parotid tumour with ipsilateral facial nerve paresis presented in 1988

The first, a 67-year-old man, presented with a 7-week history of a right-sided facial nerve palsy affecting all but the temporal branches of the nerve There was an associated right-sided parotid swelling which had been present for some years. The swelling was soft and painless, but there was some suggestion that it had recently enlarged

A superficial parotidectomy was performed and the patient made an excellent postoperative recovery. Three months later his facial nerve paresis had almost completely resolved Histology subsequently reported an adenolymphoma (Warthin's tumour) with no evidence of malignancy

The second patient was a 34-year-old woman who presented with a 2-month history of left facial paresis associated with a parotid mass which had been present for 3 months CT scan confirmed a deep parotid tumour. ACTH was administered and some nerve function was regained before surgery Parotidectomy was performed for a pleomorphic adenoma. The facial nerve was preserved with the exception of the cervical branch which was enmeshed in the tumour. The resected branch was immediately repaired by nerve graft

Three months after surgery complete resolution of the paresis had occurred with the exception of some residual weakness in the distribution of the cervical branch

These two patients, together with the previous report, highlight the requirement to judge each case on its merits, it can no longer be said that facial nerve involvement is ‘proof positive’ of malignancy in parotid swellings.

Heller's myotomy

Sir

Crookes, Wilkinson and Johnston (*Br J Surg* 1989; **76** 99–100) are to be commended on their attempts to ensure competency of the cardia after a modified Heller's myotomy for achalasia Their careful follow-up with the absence of heartburn in any of their patients postoperatively and the documentation of normal oesophageal acid exposure in five of six patients on 24-h pH monitoring gives objectivity to their conclusion. The debate over the need for reflux protection after a Heller's myotomy has gone on for many years and there have been a number of alternative solutions proposed. As the authors point out, by limiting the myotomy to the oesophagus, Ellis and co-workers claim an absence of gastro-oesophageal reflux[1]. However, their impression is not supported by pH monitoring Although Crookes *et al.* have described what they consider is a novel approach there have been two previously described partial fundoplications that have been specifically designed to be used during a Heller's myotomy. The first is the Dor procedure in which a flap of gastric fundus is laid anteriorly over the myotomy, with interrupted suture of the flap to the edges of the myotomy[2]. This method applies the partial wrap to the area that would have been left open by the operation described by Crookes *et al*

The second partial fundoplication is that described in 1963 by Toupet[3] in which a posterior wrap of very similar dimensions was applied to the oesophagus in a similar fashion to that described by Crookes *et al.*, both as a primary anti-reflux operation and also for anti-reflux protection after a Heller's myotomy. Currently a partial wrap is to be preferred because the aim of surgery in achalasia is to reduce the outflow resistance of the oesophagus to allow food and liquid to pass through by the effect of gravity and any anti-reflux procedure must not add to that resistance.

In our opinion the Dor procedure is to be preferred because it has the advantage that the wrap is applied to the area in which the sphincter defect has been created, thus transmitting the changes in intra-abdominal pressure directly to the mucosa of the lower oesophagus. It also protects the exposed area of mucosa. It achieves the same effect as the Toupet or Crookes procedure in maintaining the separation of the myotomized muscle and can be performed without circumferential dissection of the lower oesophagus

The most extensive publication of this procedure in the English language is that of Csendes who has recently described a series of 100 consecutive Heller procedures with the Dor type of reflux protection[4]. He documented an absence of reflux symptoms in all except one patient and demonstrated a positive standard acid reflux test in 19 per cent, a similar figure to that reported by Crookes.

While commending the report of Crookes *et al*, we would suggest that the Dor procedure is simpler and safer while being equally effective.

Acute lower limb ischaemia

Sir

We read with interest the article by Walker and Giddings (*Br J Surg* 1988; **75** 1189–92) concerning the use of streptokinase and surgery in the treatment of acute lower limb ischaemia However, we feel that there are several points that require clarification

In order to allow comparison between this series and others reported in the literature, it is important to know what exclusion criteria are used. Specifically, did they exclude all patients with a previous history of cerebrovascular accident or only those with a recent history of less than 2 months[1]? Similarly, did they exclude patients older than 75 years (listed as a relative minor contraindication in the NIH criteria[1])? They state that 56 patients with subacute ischaemia were treated with heparin alone, but do not detail the length and duration of ischaemia or its severity, the ankle pressure and/or ankle·brachial index or whether any tissue necrosis was present. On what grounds were they selected for heparin alone rather than arteriography with a view to thrombolysis or surgery, and what was their outcome?

How many patients were excluded from this study following failure to position the catheter for thrombolysis adequately, and what was their outcome?

In their discussion, it is suggested that proximal stenoses should be dilated first and then the distal thrombus perfused, with the catheter presumably lying within the dilated 'thrombogenic area'. How many patients required this technique and how often did this area require thrombolysis itself before the catheter could be safely withdrawn?

Finally, the authors inadvertently included a case of brachial occlusion in this article However, this is another interesting application for low-dose intra-arterial thrombolysis and therefore we would appreciate a few more details. Which approach did the authors use and what was the aetiology of the lesion?

Authors' reply

Sir

We are pleased to reply to the comments of Mr Berridge and Dr Gregson.

We excluded patients who had suffered a cerebrovascular accident within the previous 2 months and those who had had surgery within the previous 3 weeks, but not patients greater than 75 years of age. As stated in our protocol, all patients had ischaemia of greater than 12 h duration and all of those treated with heparin alone had already undergone diagnostic arteriography, which we regard as essential before a choice of treatment is made. As the protocol states, patients with calf muscle necrosis were treated by primary amputation One patient with a blocked femoropopliteal graft could not be given the infusion because the catheter could not be passed into the strictured origin of the graft and this patient was managed surgically. The number of proximal dilatations was not separately recorded but some required exit thrombolysis and no complication ensued The case of brachial occlusion was from our first series and was due to cardiac embolus The catheter was passed from the groin. We do not have sufficient experience of this technique in the upper limb to suggest a protocol at present.

Incisional hernia

Author's reply

Sir

Mr A E Kark (*Br J Surg* 1989; **76** 104) needs only to look back at page 59 of the same volume to find that you discourage the provision of references in 'Surgical workshops'. There are important differences (*Br J Surg* 1988, 75: 1149) between Boerema and the paper to which he refers, but he would first have to be able to understand the difference between a Bassini and a Shouldice How relevant is his statement that nylon sutures do not eliminate infection when those recommended are absorbable, or his reference to skin infection when the method described (not Boerema's) has virtually eliminated it? Who is going to try Boerema's operation if a vociferous protagonist admits to serious skin infections but persists 38 times to discover this, and does not recommend dieting as an important preliminary to operation in the obese?

Cognoscenti of the literature on the treatment of incisional hernia will recall the dismal but honestly reported results from a British centre of excellence which shall remain nameless. There is no room for complacency. Boerema's operation has not entered British texts and should not do so

Growth rates in hepatic metastases

Authors' reply

Sir

We would like to thank Messrs Pritchett and Coleman (*Br J Surg* 1989; **76**. 206) for their interest in our paper 'Growth rates in hepatic metastases' (*Br J Surg* 1988; **75**· 641–4) They have correctly identified a proofreading error which resulted in a plus sign missing from the volume formula While we accept the comment 'that a volume formula should contain three length dimensions', this was not possible in our study because the 'slicing' distance of the CT scanner used was insufficiently narrow to give a meaningful third dimension. We did, however, make the observation that small metastases were sausage-shaped and not spherical, hence our selection of formula

In response to the second question, there was no arbitrary selection of data points. When only two points were used for analysis it was because the other scans were indistinct. When more than two scans were utilized, a linear regression analysis was employed

The present study was not designed to test the hypothesis 'that human colorectal carcinoma exhibits Gompertzian growth'. This would require several scans on many metastases in individual patients. It may be of interest, however, that we now have three patients who have had five or more scans studying several metastases, and it would appear that Gompertzian growth kinetics most closely fit the observed pattern of growth

The correlation coefficient value is +0·91. We concede that if the single data point referred to was removed then the statistical analysis would be different. We also accept that there may be an argument for removing it, but it was for this reason that we chose to present all the data, tedious as it may seem, in tabular form. The reader could then draw his own conclusions.

We believe that this, however, is peripheral to the message that we wish to present Messrs Pritchett and Coleman are entirely correct when they say that the distinction between overt and occult metastases is artificial We used the term 'occult' to indicate metastases which were not recognized by the surgeon but were identified by other techniques. This had an important implication for our understanding of the natural history of the disease, because when we first used the term it was thought that deaths after curative surgery were due to venous dissemination of neoplastic emboli at the time of laparotomy Clearly very small tumour deposits on the liver surface might be detected by the surgeon as 'overt' metastases, while large deposits deep in the substance of the liver might be missed but detected by CT or intraoperative ultrasound as 'occult' metastases Hence any distinction between 'occult' and 'overt' is artificial

The message in the present paper is a simple one Recent studies show that few patients who do not have 'occult' metastases demonstrated by CT at the time of surgery or intraoperative ultrasound subsequently die from the disease If these 'occult' and 'overt' metastases are in most cases at least 1 cm in diameter at that time, then the metastatic process must have taken place long before the patient became symptomatic. Indeed, careful consideration of the data might suggest that colorectal cancer behaves consistently as a metastasizing or non-metastasizing variant from an early stage in the natural history

Suction drains

Sir

The method for securing suction drains described by Stacey-Clear and Heddle (*Br J Surg* 1988, **75**· 1195) is not new We have been using this method routinely for more than 20 years We believe it was first described by the late Mr F N. Cort, who showed it to us

Our technique differs slightly from that described in their paper. A small length of the end of the suction drain tubing is cut off from the end of the drain. The drain is then placed in the wound with a loop of skin suture through the end hole of the suction drain tubing The suture is then passed through the small separate piece of suction drain tubing and is tied loosely with the piece acting as a bridge on the skin surface. This not only prevents the suture from being tied too tightly, but identifies it to the nursing staff who can recognize it easily when it comes to removal of the drain

We use this method routinely in the securing of all suction drains, except following thyroid and parathyroid surgery where the tip of the drain lies deep to the strap muscles We have found it to be very successful and recommend it for general use.

Ceruletide and management of retained common bile duct stones

Sir

There is at present only limited published data on the value of ceruletide in the management of retained common bile duct stones. We were therefore surprised that Dr Tritapepe and colleagues (*Br J Surg* 1988, **75**. 144–6) did not mention the Liverpool experience of this technique in their discussion[1]. We would agree that this method of stone removal is safe and theoretically attractive, but we were disappointed with its use in practice. Using the same dose of ceruletide and similar volumes of saline infusion as those described by Professor Cuschieri[2], we were only successful in removing small stones (less than 8 mm) from three of ten patients. These results are probably no better than might have been achieved had we used saline infusion alone It is worth remembering when evaluating this or similar methods of stone removal that a number of common duct stones are able to pass on their own The addition of mono-octanoin to dissolve stones partially before repeat administration of ceruletide and saline is interesting but the whole appeal of this technique, namely its simplicity, is thereby rather lost

Variceal haemorrhage

Sir

We think Mr Jenkins and Professor Shields (*Br J Surg* 1989, **76**: 49–51) do emergency oesophageal transection a disservice when they conclude that it is of little use in patients whose bleeding cannot be controlled by conservative measures, and that good results can only be expected in patients with good liver function In their review of a 'planned management policy' it is clear that all their patients had sclerotherapy and transection was used as a last resort in patients whose bleeding could not be controlled by injection It is not stated how many sessions of variceal injection or number of episodes of rebleeding constituted 'failure of sclerotherapy'

Terblanche's group[1] has shown that the use of three injection sessions to control bleeding during the same hospital admission results in nearly 100 per cent mortality They recommend a maximum of two sessions and if bleeding continues transection or other surgery.

In our prospective randomized study of emergency oesophageal transection *versus* injection sclerotherapy in patients with cirrhosis who had failed conservative measures for control of bleeding (over half were Pugh's grade C), we found no difference in mortality between the two techniques and also concluded that no more than two sessions of emergency injections should be used to control bleeding[2]. In addition we found that transection was better in controlling bleeding Two other randomized studies not cited by Mr Jenkins and Professor Shields also conclude that transection has a role Huizinga *et al.*[3] found that transection was superior to sclerotherapy in controlling bleeding with a similar mortality rate Teres *et al*[4] found that transection was preferable to portacaval shunt in well-compensated cirrhotics In decompensated cirrhotics survival was similar to those receiving sclerotherapy, despite a 71 per cent rate for control of bleeding with transection—the lowest recorded in the literature.

We would suggest that emergency oesophageal transection does have a part to play in the management of patients with bleeding oesophageal varices, but that it must be employed early in the management It should be used either *ab initio* or after a maximum of two attempts at sclerotherapy have failed. To continue sclerotherapy beyond this is to court disaster.

Emergency oesophageal transection is a valuable and viable technique but must be used at the right time

Authors' reply

Sir

Thank you for letting us have an opportunity to reply to the letter from Dr Burroughs, Mr Hamilton and Professor Hobbs in response to our article We fear that the correspondents have missed the point of our article. We did not seek to condemn oesophageal transection and indeed advocate its use in certain circumstances The purpose of our paper, which we described in the introduction and repeated in the discussion, was to emphasize that if the operation was reserved to a late stage in a sequential management policy and therefore carried out only after the patient had been bleeding for some time, the results would be poor Indeed, we advocated that surgical treatment should be instituted as early as possible to prevent the deterioration associated with prolonged conservative management. Our current practice is that if the bleeding continues despite two sessions of adequate sclerotherapy, plus adjuvant treatment including somatostatin and balloon tamponade, we have recourse to operation.

We did not refer in detail to their prospective randomized trial comparing emergency oesophageal transection and injection sclerotherapy in cirrhotics, because, as far as we are aware, it has been published in abstract form only and thus defies detailed analysis. The authors, however, cannot be seriously advocating that every patient admitted with an acute variceal haemorrhage should be considered equally for oesophageal transection or injection sclerotherapy. An operation of this magnitude should only be carried out as initial treatment if there are reliable predictors of recurrent haemorrhage, but, sadly, these are often lacking

We have re-read the article by Huizinga, Angorn and Baker[1] and cannot reconcile the 87.5 per cent mortality rate which they report, when the operation is performed in emergency circumstances, with the sentence in the above letter There is a whole world of difference in outcome, when operation for oesophageal varices is carried out in an emergency, compared with elective circumstances Moreover, in the paper by Teres *et al.* it is difficult to determine what was emergency and what was elective treatment, for '80 per cent of patients were 'randomized' at the time of variceal bleeding within 3 weeks of hospital admission for variceal bleeding'. This definition of emergency treatment of acute variceal bleeding is considerably different from ours and, we assert, most others working in this field

Emergency oesophageal transection is a valuable technique, which we emphasized on several occasions in our paper Timing, however, is of the essence and we cannot accept that it should be considered equally with injection sclerotherapy as the very first treatment to be carried out when the patient is admitted to hospital. We believe that most gastroenterologists would agree with this view until clear predictors of recurrent haemorrhage are identified.

Preoperative cardiac risk of aortic aneurysm surgery

Sir

We read with interest the paper by Fletcher *et al.* on the risk of aneurysm surgery as assessed by preoperative gated heart pool scan (*Br J Surg* 1989; **76**: 26–8) We, like the authors, concur that left ventricular ejection fraction (LVEF) is an accurate preoperative risk predictor of postoperative cardiac complications[1] However, despite their assessment of risk, three patients with LVEF of greater than 45 per cent developed postoperative congestive cardiac failure We feel that this figure is unacceptably high. The authors also state that, owing to pressure on intensive care beds, it was not possible to use preoperative pulmonary artery catheterization routinely

We have previously shown that all patients undergoing abdominal aortic surgery do not require pulmonary artery catheterization[2]. It has been our policy at The Wellesley Hospital to measure LVEF on all patients undergoing such surgery routinely. Patients with LVEF of less than 50 per cent are selected for pulmonary artery catheterization Catheters are inserted on the morning of surgery and Starling curves are constructed. Based on this derived haemodynamic data, optimal cardiac performance is maintained throughout. In a series of 66 consecutive patients, postoperative cardiac complications occurred only in patients with LVEF of less than or equal to 30 per cent

We feel that all patients undergoing abdominal aortic surgery should have preoperative assessment of left ventricular function by radionuclide means. Once the high-risk patient has been successfully isolated, optimal cardiac performance must be maintained throughout the perioperative period. This high-risk group should not be denied the benefit of perioprative central haemodynamic monitoring

Carotid body tumours

Sir

We read with interest the paper by McPherson *et al.* (*Br J Surg* 1989, **76** 33–6) on their excellent results obtained in treating patients with carotid body tumours and other cervical paragangliomas It is noteworthy that the oldest patient operated on in the series was 61, and the median age for the group was 47 While the morbidity and mortality rates associated with resection of carotid body tumours have decreased in recent years, it is still a hazardous operation in the elderly Although the authors mention the natural history of carotid body tumours, we were surprised that they did not indicate that there may be a role for observation alone in selected cases for this slow growing tumour which rarely metastasizes

Over a 33-year period we have had three patients with carotid body tumours who refused operation and six who were considered unresectable at operation These patients have been followed up for a median

Table 1 *Outcome of patients with untreated carotid body tumours*

Reference	No of patients	Median follow-up	Outcome
Farr[1]*	7	> 10 years	All alive with disease
Krupski *et al* [2]	3	8–10 years	All alive with disease
Lack *et al.*[3]	3	10 years	One patient dead (13 years) from unrelated cause
Shamblin *et al* [4]	13	Not published	All alive with disease
Dickinson *et al.*[5]†	7	Not published	All alive with disease

*One patient lost to follow-up; †three patients lost to follow-up

of 7·5 years (range from 6 months to 15 years) Eight of the nine have stable disease, one has clinical evidence of progression, and all are asymptomatic. This information, combined with that from other series (*Table 1*) has led us to recommend observation alone for these tumours in elderly or high-risk patients

Treatment of cancer of the colon

Sir

In response to the published preference of Mr Marston for a subtotal colectomy and ileorectal anastomosis in every case of colonic cancer (*Br J Surg* 1989; **76**· 71), we wish to emphasize the following points.

1. The maximum published incidence of metachronous tumours is 10·2 per cent[1], and it may be argued that the policy of routine subtotal colectomy involves an unnecessary resection in 90 per cent of these patients.
2. Colonic cancers are maximally distributed in the sigmoid and rectosigmoid junction[2] and therefore many of these may require resection of varying portions of the rectum as well, and thus require more than a subtotal colectomy.
3. Suture line recurrence owing to implantation of exfoliated malignant cells within the lumen is uncommon and, in any event, is unlikely to be influenced by the length of bowel resected[3]. On the other hand, lymphatic and hepatic spread, which chiefly governs the prognosis[4], is certainly not influenced by the extent of resection. Unlike oesophageal cancer, which has documented submucosal spread[5], colon cancer has much less predilection to mucosal and submucosal spread.
4. As extracolonic disease is the problem, these patients cannot be spared 'the expensive and cumbersome process' of tumour marker estimation and other surveillance for tumour recurrence.
5. The quoted figure for anastomotic leakage rate following colocolic anastomosis is 4 1 per cent[6] At our centre, one of 30 patients in the 2 years from 1987 to 1988 had leakage This is sufficiently low to warrant continuation of the procedure
6. In our centre, five of 15 patients operated on in 1988 for colonic cancer were under 40 years What does the author suggest be done if a patient undergoing a right colonic resection at, say, 36 years develops a second malignancy in the rectum, a terminal ileostomy, or an ileal pouch–anal anastomosis?
7. Even in obstructed left colon cancers, the role of subtotal colectomy has been limited by the use of on-table colonic lavage and primary colocolic anastomosis[7].
8. Last, follow-up sigmoidoscopy in patients who have undergone ileorectal anastomy, and who have liquid faeces obscuring the field, is not always an easy task.

In the light of the above, we think that the author, by choosing the option of a subtotal colectomy with ileorectal anastomosis for cancer of the colon, will certainly leave the patient 'loose' but no more likely to be living than had he undergone a conventional colonic resection

Amputation for peripheral vascular disease

Sir

We applaud the efforts of Messrs McCollum *et al* (*Br J Surg* 1988; **75**: 1193–4) to reduce the ratio of above-knee to below-knee amputations, but are concerned about the very large numbers of major limb amputations performed over a 15-month period. Furthermore, the ratio of above-knee to below-knee amputation is not only determined by the decisions and skill of the surgical team but also by the state of the leg to start with!

We have shown that vascular reconstruction can reduce the number of lower limb amputations by up to 80 per cent in two separate series conducted in the West Midlands over the last 4 years.

In one hospital the mean major limb amputation rate was 55 per year from 1980 to 1984. Following introduction of an intensive limb salvage policy using proximal and distal vascular reconstruction this rate fell to 11 per year despite 142 critially ischaemic legs being treated in 1985 and 1986.

In the second hospital the mean major limb amputation rate in 1984/85 was 48 per year; after instituting a similar reconstructive policy the major limb amputation rate for 12 months in 1987/88 was 16 out of 71 critically ischaemic legs which presented for treatment

Data collected from these studies shows that the rehabilitation of reconstructed patients is faster, more complete and less expensive than those undergoing major limb amputations. It is clearly necessary to train more vascular surgeons in small vessel surgery so that the number of major limb amputations performed for peripheral vascular disease in this country can be drastically reduced.

alcifectomy for ductal carcinoma in situ

Sir

The article by Wobbes *et al.* in the February issue of the Journal (*Br J Surg* 1989; **76**: 185–6) discusses the problem of ductal carcinoma *in situ* They state that microcalcifications may be the only sign of the lesion and that the biopsy procedure is aimed at removal of all microcalcifications. If a breast conserving operation is performed, the removal of the microcalcifications with free margins, and confirmation by specimen radiography to verify that microcalcifications have been removed, may be the only procedure necessary. The name of this procedure is microcalcificectomy[1] or calcificectomy (kăl'sĭ-fĭ-sek'tŏ-mi) or simply calcifectomy It is an accurate description of this operation which no doubt will be increasingly performed in the conservative treatment of ductal carcinoma *in situ*.

Breast abscesses

Sir

In their recent correspondence (*Br J Surg* 1989; **76**: 103), Mr Nash and Mr Powles indicate that many non-lactating breast abscesses associated with periductal mastitis are sterile on culture This is incorrect. With appropriate culture techniques, bacteria can be isolated from most, if not all, non-lactating abscesses[1] A combination of cephradine and metronidazole covers the majority of organisms isolated from these lesions.

I agree that breast abscesses can be treated by aspiration combined with appropriate oral antibiotic treatment[2]. It is important to note that in lactating breast abscesses, pus usually reaccumulates and multiple aspirations may be required

Paget's disease

Sir

We read with interest the recent paper by Armitage *et al* (*Br J Surg* 1989, **76**· 60–3). This was a review of eight patients with anal Paget's disease since 1930 They concluded that the association with colorectal tumours may have been exaggerated in previous studies due to confusing Pagetoid spread from an underlying anorectal adenocarcinoma with true Paget's disease.

We agree with Armitage *et al.* as we have treated two cases of anal Paget's over the last 3 years, neither of whom had associated malignancy. The first required an anterior resection for a tubulovillous adenoma which showed mild dysplasia, but there was no evidence of malignancy Both have required local excision of the extramammary Paget's which as yet have been curative.

Stainless steel	220 (142–407)	159 (114–337)
Polypropylene	399 (144–698)	144 (97–243)

Book reviews

Amputations and Prostheses. 2nd edition.

M. Vitali. 192 × 260 mm Pp. 217 Illustrated. 1986. London Baillière Tindall. £21 00

The second edition of this book has been extensively updated and makes an excellent contribution to amputation surgery and prosthetics. For too long these subjects have remained isolated from each other and their practitioners are largely ignorant of the problems relating to the other field. If a surgeon routinely carries out amputations without any consultation with those who are responsible for the patients' subsequent rehabilitation then he is out of touch with reality This book underlines the necessity of preoperative consultation and stresses the advantages of such a policy. A good example of this is that preoperative consultation may draw attention to the fact that a patient may be unlikely to walk again and therefore would be better off with a through-knee or Gritti–Stokes amputation rather than the usual above-knee operation. The authors emphasize that patients with bilateral above-knee stumps find it difficult to turn over in bed The quality of the patient's life can be much improved by a more distal amputation.

The opening historical review is full of interesting detail, including reference to the description by Hippocrates of amputation by disarticulation at the knee The famous wooden leg of the Marquis of Anglesey is also mentioned, but a recent comment in Anglesey that the design of artificial legs has not improved much since the early 19th century is omitted for obvious reasons! There follows an illuminating chapter on gait analysis, a subject which is bound to develop in the near future as it is relevant not only to amputees but also to those with neurological problems Prosthetics and individual amputations are exceptionally well described, a good analysis of the advantages and disadvantages of each amputation is given and always with a view to rehabilitation.

There are possibly only two minor criticisms. First, it would have been helpful to have included a fuller description of the skew sagittal flap below-knee amputation with gastrocnemius and soleus muscle myoplasty; second, in the final chapter on future developments, perhaps more could have been made of the importance of having all patients with critically ischaemic limbs seen by vascular surgeons in order to reduce the number of amputations which currently total 5000 each year These are, however, minor criticisms which in no way detract from an excellent book which should be read by all those involved in this branch of surgery. Such study would surely improve the ultimate outcome for these unfortunate customers

Perspectives in Colon and Rectal Surgery

T R. Schrock. 70 × 100 mm. Pp 152 Illustrated 1988 St. Louis Quality Medical Publisher Inc. $193.00

In the Preface, the Editor, Theodore Schrock, states that the originators of the text set out to produce a hybrid of book and journal for colon and rectal surgeons. I am tempted to say that in so doing they have fallen between two 'stools', but I realize that this is a cheap jibe and is not entirely correct The contributors are eminent in their field, and have put together a most readable first edition of a series which hopes to be biannual and topical The articles are crisp and to the point and well laced with the authors' personal experience The latter is refreshing and in a text of this nature is most fitting. The contents are a mixture of review type articles dealing with current topics and more personal viewpoints of difficult management problems or new techniques Although the review articles are excellent, I felt at times that the discussion of several controversial topics was 'thin' and would have benefited by more in-depth appraisal While one appreciates the publisher's desire to reduce the typescript, this could have been achieved by the elimination of the 'sideline' contributions The latter, entitled 'On being an editor or contributor in medical publishing', although most informative, seemed out of place in a book of this nature Hopefully, the next edition will have something a little more relevant in this section.

On balance, this new series of mini-books presents an innovative way of supplying current information about a rapidly expanding speciality. The question the publishers wish to answer is whether I am prepared to buy it. Whereas the content is certainly worthwhile, I coul not justify to my bank manager the purchase of two thin hardback books each year For a text of this length, supplying a limited amount of information, the publishers would be well advised to produce a cheaper 'paperback' version. If they did so, I am sure that it would become a popular addition to the library of most surgeons with an interest in colorectal disease.

Diseases of the Veins
Pathology, Diagnosis and Treatment

N. L. Browse, K G. Burnand and M. L. Thomas. 192 × 252 mm. Pp. 67 Illustrated 1988 London Edward Arnold £130 00

The notable advances in phlebology in recent years have not been matched by the availability of major textbooks. This prompts a wider question How does one obtain effective training in phlebology? Rarely does general surgical training provide a proper experience of laboratory tests, specialist radiology and surgical techniques which have lately become part of the management of complex venous disorders Even in most vascular units venous disease tends to receive short shrift, as surgeons seek to stem the rising tide of ischaemic legs and aneurysms Surely if vascular training is to mean anything it should provide a surgeon capable of giving expert care for patients with a range of vascular problems which includes complicated venous and lymphatic diseases. These are more difficult to manage than arterial disease. Of course, primary varicose veins do not demand specialist care, but even here the scope for improved management is immense.

Consider the trainee surgeon, often unsupervised, coming up for air amid the thronged varicose vein clinic, scratching his brow over chronically ulcerated legs or toiling over the venous remnants of the operating list What should be his *vade mecum*? Much has changed since the last edition of that familiar classic from the same stable 'Dodd and Cockett'.

Having established the need, is this book the answer? The aim was to produce 'a practical readable book containing something for medical students, residents and consultants' A modest enough aim, which in the event has been exceeded It begins very well with a canter past the venous milestones in medical literature, beginning in 1550 BC and tactfully reigning in at 1960 It goes on to deal with virtually every venous disorder except portal hypertension, intracranial diseases and piles

The anatomy, physiology, radiology and laboratory methods are authoritatively covered and well illustrated The clinical chapters are rich in practical detail and the references which may number up to 345 per chapter are up-to-date An excellent chapter on pulmonary embolism is contributed by Dr Graham Miller The section on chronic leg ulcers is much enhanced by coloured plates.

A reviewer likes to find something to carp about Why one illustration shows stripping from ankle to groin when the text (rightly in my view) advocates knee to groin was not clear. Perhaps it was part of the authors' attempt to offer a balanced assessment of the options Fortunately this is not too balanced, and the reader is seldom left with uncertainty or indecision (unlike many other large textbooks), for the text is liberally spiced with pithy comments and positive opinions highly relevant to patient care.

My main criticism of this book is its 'utility' presentation which is not up to modern publishing standards and which does less than justice to the text The pages appear somewhat crowded and the visibility of figures and print through the poor quality paper undoubtedly detracts from the quality.

Although many textbooks are to be equally admired for their erudition few are such a positive pleasure to read This book abounds in practical clinical common sense. Both comprehensive and erudite, it escapes the greyness of multiauthorship It cannot fail to be pre-eminent in the field for a long time to come.
